Introduction

Pancreatic diseases frequently induce not only pancreatic exocrine insufficiency (PEI) but also endocrine impairment, which result in the development of diabetes mellitus. Diabetes from exocrine pancreatic disease, namely, pancreatic diabetes or type 3c diabetes, is categorized as secondary diabetes that is associated with various pancreatic diseases, such as acute or chronic pancreatitis and pancreatic cancer, as well as pancreatic resection [1–9]. Although type 1 diabetes and type 2 diabetes are well studied, research on pancreatic diabetes is limited, and its characteristics remain unclear. Sustained inflammation and fibrotic change due to pancreatic diseases lead to β-cell loss and reduced insulin secretion, and this is the most common pathogenesis of pancreatic diabetes. In addition, the levels of pancreatic counterregulatory hormones, such as glucagon, are decreased in these patients. Malnutrition resulting from PEI should also be monitored. Therefore, recognizing the differences between pancreatic diabetes and other types of diabetes is very important to achieve good glycemic control and ensure an appropriate quality of life in patients with pancreatic diabetes.

Definition, Prevalence, and Etiology of Pancreatic Diabetes

The American Diabetes Association (ADA) categorizes pancreatic diabetes as a "specific type of diabetes due to other causes" and distinct from type 1, type 2, and gestational diabetes. Pancreatic diabetes includes both structural and functional loss of glucose-normalizing insulin secretion due to pancreatic exocrine dysfunction [1]. It has been called "type 3c diabetes" that is derived from diverse etiologies including pancreatitis (acute, chronic, or hereditary), pancreatic trauma, pancreatectomy, neoplasia, cystic fibrosis, hemochromatosis, and fibrocalculous pancreatopathy. However, the most common cause of pancreatic diabetes is chronic pancreatitis. In routine clinical practice, patients with pancreatic diabetes have been misdiagnosed as having type 2 diabetes.

The prevalence of pancreatic diabetes among all types of diabetes in Western populations has been reported to be 5–10% [4,6]. Ewald et al. [10] studied 1868 patients diagnosed as having diabetes over a 2-year period and reported that 172 of these patients (9.2%) could be classified as having pancreatic diabetes. In contrast, a nationwide survey in Japan revealed that patients with true pancreatic diabetes (newly developed diabetes associated with pancreatic disease) who received treatment in 2005 accounted for only 0.8% of all patients with diabetes [11]. A more recent large retrospective cohort study from England revealed 559 out of 31,789 new diagnoses of adult-onset diabetes were cases of diabetes following pancreatic disease (1.8%) [12]. Although the prevalence of pancreatic diabetes differs among studies, clinicians should always consider the possibility of pancreatic diabetes when they first make a diagnosis of diabetes. If the accurate diagnosis of pancreatic diabetes and prognosis of pancreatic disease improve, the prevalence of pancreatic diabetes may increase in the future.

Chronic pancreatitis has been well recognized as a major cause of pancreatic diabetes, but a cohort study in New Zealand found that acute pancreatitis is the most frequent preceding disease. In that study, acute pancreatitis

Companion website: www.wiley.com/go/beger/thepancreas4e

accounted for 61% of the overall prevalence of diseases of the exocrine pancreas [13]. In another study by Ewald et al. [10], the underlying pancreatic diseases included chronic pancreatitis (78.5%), pancreatic cancer (8.1%), hereditary hemochromatosis (7.0%), and cystic fibrosis (4.1%), as well as pancreatic resection (2.3%). Ito et al. [11] reported that the causal factors of pancreatic diabetes were chronic pancreatitis (40.0%), pancreatic cancer (24.6%), pancreatectomy (10.2%), acute pancreatitis (7.5%), and autoimmune pancreatitis (6.1%).

Patients with chronic pancreatitis frequently have diabetes as a comorbidity, even though its occurrence varies widely from 5% to >80% [2,14–16]. In a study conducted in the United States, 383 out of 1171 patients (32.7%) with chronic pancreatitis had diabetes [17]. A multicenter Italian survey also reported endocrine insufficiency in 31% of patients with chronic pancreatitis [18]. The duration of chronic pancreatitis is a well-known and significant risk factor for the development of diabetes. A large-scale study from China that included 1633 patients revealed a cumulative rate of diabetes mellitus of 21.7% at 10 years after the diagnosis of chronic pancreatitis [19]. In a follow-up survey of patients with chronic pancreatitis without diabetes, 121 of 418 patients (28.9%) were newly diagnosed as having diabetes over a period of 8 years [20]. A recent nationwide epidemiological survey of chronic pancreatitis in Japan also showed that patients with advanced-stage chronic pancreatitis (definite/probable cases) had a higher proportion of diabetes than did those with early-stage chronic pancreatitis (42.3% vs. 19.3%) [21]. A systematic review and meta-analysis involving 8970 patients from 15 studies reported that the incidence of new-onset diabetes after chronic pancreatitis diagnosis was 30%. The prevalence of newly diagnosed diabetes was 15% within 36 months, and it increased to 33% after 60 months from the diagnosis of chronic pancreatitis [22]. Therefore, the prevalence of pancreatic diabetes and chronic pancreatitis as an underlying disease seems far underestimated because many patients with diabetes do not undergo any evaluation of pancreatic exocrine diseases and many patients with chronic pancreatitis do not undergo any evaluation of diabetes.

Risk Factors for the Development of Diabetes in Chronic Pancreatitis

The risk factors for diabetes in patients with chronic pancreatitis include alcohol consumption, smoking, and pancreatic calcification, which are also the risk factors for the progression of chronic pancreatitis [11,21,23,24]. Alcohol consumption was the most common cause of chronic pancreatitis, and it accounted for 72.0% of cases in a recent nationwide survey in Japan [21]. Ito et al. also reported that alcohol consumption was the main causal factor for chronic pancreatitis in patients with pancreatic diabetes (77.3%, 231/299) [11]. In a long-term study of 2037 patients with chronic pancreatitis, 28.8% (587/2037) developed diabetes during a median follow-up period of 7.6 years [24]. Furthermore, the development of diabetes was significantly earlier and more common in alcoholic chronic pancreatitis than in idiopathic chronic pancreatitis. The cumulative rates of diabetes development at 10 years after the onset of chronic pancreatitis was 29.7% and 21.7% in patients with alcoholic and idiopathic chronic pancreatitis, respectively.

Smoking is another important factor associated with the development of diabetes in chronic pancreatitis. Many reports have documented a relationship between smoking and the progression of chronic pancreatitis [21,25–29], which is inevitably associated with the development of diabetes. Maisonneuve et al. reported that smoking was associated with a significant increase in the risk of developing diabetes (hazard ratio, 2.3) after the diagnosis of pancreatitis [26]. Therefore, patients with chronic pancreatitis and diabetes should take steps to improve their lifestyle via abstinence from alcohol and smoking cessation.

Pancreatic calcification is a key finding in the diagnosis of chronic pancreatitis and is involved in disease progression. Several studies have revealed a correlation between pancreatic calcification and the development of diabetes [7,20,23,30]. The risk of diabetes increased 1.32-fold after the onset of pancreatic calcification [20]. A study from China also revealed pancreatic calcification as a risk factor for the development of diabetes mellitus (hazard ratio, 2.326) [30]. Therefore, it is important to recognize pancreatic calcification not only as an indicator of advanced chronic pancreatitis (exocrine insufficiency) but also as an indicator of impaired pancreatic endocrine function.

Clinical Characteristics of Pancreatic Diabetes

Pancreatic diabetes is characterized by the impaired synthesis and secretion of insulin from β cells and glucagon from α cells because of primary pancreatic diseases [20]. Furthermore, PEI resulting from the decreased secretion or outflow obstruction of pancreatic juice induces the impaired absorption of glucose. Since the degree of impairment in pancreatic endocrine and exocrine functions differs in each patient,

the pathophysiology and treatment of pancreatic diabetes are complicated. Pancreatic diabetes is also known as "brittle diabetes" because the fluctuations in blood glucose levels result in unstable glycemic control.

Recently, Fukuda et al. reported that the incidence of diabetes was significantly higher in patients who underwent distal pancreatectomy than in those who underwent pancreatoduodenectomy despite no significant difference in the volume of the resected pancreas between the two groups [31]. They also revealed significant alterations in the gut microbiome and increased secretion of glucagon-like peptide-1 (GLP-1) in patients who underwent pancreatoduodenectomy, which possibly protected against the development of diabetes. This study shed light on the pathogenic mechanism of pancreatic diabetes, but further validation studies are warranted in the future.

Evaluation and Diagnosis of Pancreatic Diabetes

PEI

Patients with pancreatic diabetes, especially those with chronic pancreatitis, frequently have accompanying PEI, which results in some degree of fat malabsorption and malnutrition [16]. Severe PEI can lead to overt steatorrhea and weight loss that may decrease the quality of life of patients with pancreatic diabetes. Therefore, the evaluation of pancreatic exocrine function and appropriate pancreatic enzyme replacement therapy (PERT) are mandatory for these patients. Although accurate evaluation of PEI is difficult, diagnostic tests including the fecal elastase-1 or *N*-benzoyl-L-tyrosyl-p-aminobenzoic acid test are recommended if available [16]. Evaluating the patient's symptoms, including abdominal bloating or discomfort, diarrhea, and weight loss, at each follow-up visit and performing blood tests, including those for hemoglobin, total protein, albumin, and total cholesterol levels, are important for the evaluation of PEI.

Diagnosis of Pancreatic Diabetes

As in other type of diabetes, pancreatic diabetes is diagnosed on the basis of plasma glucose (PG) levels and hemoglobin A_{1c} (HbA_{1c}) analysis. A fasting PG level ≥126 mg/dL, 2-h PG level ≥200 mg/dL during a 75-g oral glucose tolerance test (OGTT), random PG level ≥200 mg/dL, or HbA_{1c} level ≥6.5% may indicate the presence of diabetes [1]. In patients with symptoms related to diabetes or those with significantly high PG levels, the OGTT should be avoided because of the increased risk of hyperglycemia. The evaluation of insulin secretory capacity, such as by using the insulinogenic index (30 min) calculated from a 75-g OGTT test, fasting C-peptide immunoreactivity (CPR), 24-h urinary CPR, or ΔCPR after glucagon injection, is also important in pancreatic diabetes, as it could help differentiate "insulin-dependent" and "noninsulin-dependent" diabetes. Determining insulin dependence is essential for choosing the appropriate medical treatment.

Pancreatic diabetes is more common than expected, and patients with pancreatic diabetes are mostly misclassified as having type 2 diabetes owing to poor awareness of this type of diabetes [4]. Moreover, no specific diagnostic criteria are available for pancreatic diabetes. Hart et al. proposed conceptual diagnostic criteria for pancreatic diabetes, which included three components: fulfillment of the diagnostic criteria for diabetes, presence of a pancreatic exocrine disease, and diabetes that is reasonably certain to be secondary to pancreatic exocrine disease [2]. Ewald and Hardt [4] also proposed diagnostic criteria for pancreatic diabetes (type 3c diabetes mellitus) (Table 56.1). The major criteria included the presence of exocrine pancreatic insufficiency, pathological pancreatic imaging findings, and absence of autoimmune markers associated with type 1 diabetes mellitus. However, distinguishing pancreatic diabetes from other types of diabetes is sometimes difficult because patients with long-standing type 1 and type 2 diabetes frequently have accompanying PEI. Therefore, clinicians should always consider the possibility of diabetes when treating pancreatic exocrine diseases, such as chronic pancreatitis and pancreatic cancer, as well as the possibility of pancreatic exocrine diseases when treating diabetes.

Table 56.1 Proposed diagnostic criteria for type 3c diabetes mellitus [4].

Major criteria (must be present)
• Presence of exocrine pancreatic insufficiency (monoclonal fecal elastase-1 test or direct function tests)
• Pathological pancreatic imaging (endoscopic ultrasound, MRI, CT)
• Absence of type 1 diabetes mellitus associated autoimmune markers
Minor criteria
• Absent pancreatic polypeptide secretion
• Impaired incretin secretion (e.g., GLP-1)
• No excessive insulin resistance (e.g., HOMA-IR)
• Impaired beta cell function (e.g., HOMA-B, C-Peptide/glucose-ratio)
• Low serum levels of lipid soluble vitamins (A, D, E and K)

Treatment of Pancreatic Diabetes

Lifestyle Improvement and Management of PEI

In patients with pancreatic diabetes, lifestyle correction through weight control in overweight patients, abstinence from alcohol, and smoking cessation should be considered as an initial treatment, as in patients with other types of diabetes. When chronic pancreatitis is the underlying cause of pancreatic diabetes, abstinence from alcohol and smoking cessation are especially important to prevent the progression of pancreatitis and achieve better glycemic control. Regarding dietary therapy, stereotypic energy restriction to improve glycemic control is not recommended as it exacerbates nutritional disorders due to PEI, which is frequently present in patients with pancreatic diabetes. The presence of PEI is of great importance, as this feature differentiates pancreatic diabetes from other types of diabetes. Patients with PEI diagnosed on the basis of symptoms, blood tests, and pancreatic exocrine function tests require adequate PERT and sufficient energy intake. The PG level is sometimes elevated after PERT; nevertheless, oral hypoglycemic agents or insulin therapies for patients with pancreatic diabetes should be considered together with appropriate PERT.

Insulin Therapy

Insulin therapy should be considered as the first-line treatment for patients with pancreatic diabetes and advanced stages of pancreatic exocrine diseases, such as chronic pancreatitis or pancreatic cancer, as well as for those who have undergone pancreatectomy [14], because these patients generally develop "insulin-dependent" diabetes. Intensive insulin therapy with long-acting insulin as a basal requirement and preprandial short- or ultra-short-acting insulin for postprandial hyperglycemia are recommended for pancreatic diabetes because these mimic physiological insulin secretion and are helpful in preventing hypoglycemia [7,9,32]. Insulin dependence in pancreatic diabetes is similar to that in type 1 diabetes mellitus, and both conditions meet the absolute indication for insulin therapy. However, compared to type 1 diabetes, pancreatic diabetes shows more impaired secretion of counterregulatory hormones for hypoglycemia, including glucagon and pancreatic polypeptide. Therefore, fluctuations in blood glucose levels are frequently observed after the injection of small doses of insulin, and this makes it difficult to achieve good glycemic control in these patients. Niwano et al. recently compared the insulin requirement between patients undergoing total pancreatectomy (pancreatic diabetes) and those with type 1 diabetes [33]. They found that the total daily insulin and basal insulin levels were significantly lower in patients undergoing total pancreatectomy than in those with type 1 diabetes. Even in the same "insulin-dependent" condition, we should pay attention to hypoglycemia more carefully in patients with pancreatic diabetes than in those with type 1 or type 2 diabetes. When good glycemic control is difficult to achieve in pancreatic diabetes, an insulin pump (continuous subcutaneous insulin infusion) could be a treatment option [33]. Moreover, adjusting the insulin dose after the evaluation of pancreatic exocrine function and adequate PERT are very important.

Therapy with Other Hypoglycemic Agents

The degree of insulin deficiency and insulin resistance varies with disease severity and duration [34]. Therefore, as in patients with type 2 diabetes, those with pancreatic diabetes who have not undergone total pancreatectomy and are not "insulin-dependent" can be administered oral hypoglycemic agents. Metformin, which is widely used in patients with type 2 diabetes and insulin resistance, is associated with a decreased risk of various cancers, including pancreatic cancer [35]. Therefore, some studies preferred metformin as the first-line treatment for pancreatic diabetes [2,16,34]; nevertheless, further validation of the effect of metformin is required. Insulin secretory agents, such as sulfonylureas and glinides, are also treatment options in patients with preserved insulin secretory capacity. However, the efficacy of incretin-based therapy using dipeptidyl peptidase-4 inhibitors and GLP-1 analogs, which also enhance insulin secretion, for pancreatic diabetes has been controversial [9,14,36]. Moreover, the tendency has been to refrain from these drugs owing to a possibility of pancreatitis [34], but several recent reports have demonstrated no relationship between incretin-based therapy and pancreatitis or pancreatic cancer [37–39]. Nevertheless, GLP-1 analogs have been associated with a high frequency of gastrointestinal symptoms as side effects [34]. Sodium-glucose cotransporter 2 (SGLT2) inhibitors, which inhibit renal glucose reabsorption and increase urinary glucose excretion [40], have recently been widely used in patients with diabetes. SGLT2 inhibitors may be a treatment option because of their insulin-independent action; however, their side effects include weight loss, which should be considered in patients with pancreatic diabetes. A recent study showed no significantly increased risk of acute pancreatitis associated with the use of SGLT2 inhibitors [41]. Although evidence regarding oral hypoglycemic agents for pancreatic diabetes is scarce, clinicians should select

appropriate drugs after evaluating the insulin secretory capacity, insulin resistance, and nutritional status, including pancreatic exocrine function, in each case.

Complications and Glycemic Target of Pancreatic Diabetes

Good glycemic control reduces the risk of microvascular and macrovascular complications in patients with diabetes [11,36]. A Japanese nationwide survey revealed that the incidence of retinopathy was lower in pancreatic diabetes than in type 1 and type 2 diabetes, but the incidence of neuropathy and nephropathy was comparable [11]. The prevalence of diabetic complications, including cerebrovascular and cardiovascular disorders, also increases with the duration of diabetes [11,14,36]. Therefore, as in other types of diabetes, achieving good glycemic control could improve the quality of life of patients with pancreatic diabetes. Conversely, rapid fluctuations in glucose levels, namely "brittle diabetes," are frequently observed in patients with pancreatic diabetes and result in poor glycemic control. Avoiding severe hypoglycemia is very important in these patients with "brittle diabetes." A large retrospective cohort study from England revealed that patients with pancreatic diabetes had worse glycemic control than did those with type 2 diabetes. The odds ratio for poor glycemic control (defined as HbA_{1c} ≥7%) at 5 years after the diagnosis was 1.7 in patients with pancreatic diabetes than in those with type 2 diabetes [12]. According to the recommendations of the ADA, less stringent targets (HbA_{1c} up to 8%) may be appropriate if the risks and burdens outweigh the potential benefits [42]. Severe or frequent hypoglycemia is an absolute indication for the modification of treatment regimens, including setting higher glycemic targets. Although this recommendation is mainly for patients with type 1 or type 2 diabetes, the same situation is frequently observed in those with pancreatic diabetes and unstable glycemic control. Therefore, less stringent glycemic control may be recommended for patients with pancreatic diabetes. Accordingly, the Japanese guidelines for chronic pancreatitis proposed that an HbA_{1c} level of 7.5% could be used as a target; nevertheless, further research is warranted to set an optimal glycemic target for this condition.

Oxidative Stress and Antioxidants in Chronic Pancreatitis

Soumya Jagannath Mahapatra and Pramod Kumar Garg

Department of Gastroenterology, All India Institute of Medical Sciences, New Delhi, India

Introduction

Chronic pancreatitis (CP) is a progressive fibro-inflammatory disease of the pancreas characterized by repeated episodes of pancreatic inflammation and injury which result in pancreatic exocrine and/or endocrine insufficiency. Morphologically, it is characterized by parenchymal loss leading to atrophy, fibrosis, and ductal stricture and/or calcification causing ductal dilatation [1]. The pathophysiological mechanisms of CP are not well understood. Over the past few decades, oxidative stress has emerged as an important mechanism contributing to pancreatic inflammation and the role of antioxidants has been evaluated in patients with CP.

Free-radical production is an integral part of cellular physiology. These free radicals are neutralized by specific cellular enzymes and other small molecules called scavengers and antioxidants. In health, intricate balance exists between free radicals and antioxidants. However, excessive production of free radicals by activation of oxidative pathways or deficiency of antioxidants tilts the balance leading to "oxidative stress." It is formally defined as "an imbalance between oxidants and antioxidants in favor of oxidants leading to disruption of redox signaling and control, and/or molecular damage" [2]. This review focuses on oxidative stress and the role of antioxidants in mitigating oxidative stress, inflammation, and relieving pain in patients with CP.

Pro-Oxidants

Pro-oxidants are the molecules that favor formation of free radicals. Free radicals have one or more free electrons and usually are reactive oxygen species (ROS) or reactive nitrogen species (RNS) in the cellular environment. Free radicals and their reaction products are a part of normal cell physiology by acting as second messengers and they play an important role in cellular signaling [3]. Mitochondria are the site of physiological oxidative stress. Excessive production of ROS and RNS may damage biomolecules such as lipids, DNA, and proteins (Fig. 57.1).

Detoxification of xenobiotics is another source of production of free radicals. Xenobiotics are toxic substances that enter the body and undergo detoxification in two phases to a hydrophilic substance thus facilitating their excretion in the urine. In phase I metabolism, cytochrome P450 (CYP 450) oxidase system and hydrolyzing enzymes either cleave the parent molecule or result in oxidation or hydroxylation. In phase II metabolism, they are conjugated to a hydrophilic group (glucuronidation, acetylation, methylation, sulfation, or conjugation with glutathione) to form a polar water-soluble inactive compound that can be excreted by the body. Induction of phase I enzymes can itself result in generation of free radicals through the CYP450 system.

Various exogenous substances such as alcohol, tobacco, environmental pollutants, heavy metals, certain drugs, dietary toxins, and fumes lead to free radical generation. Alcohol metabolism can result in production of free radicals. Alcohol is converted to acetaldehyde, a toxic and reactive molecule, by alcohol dehydrogenase, and acetaldehyde is converted to acetate by aldehyde dehydrogenase. Each of the steps results in consumption of nicotinamide adenosine dinucleotide phosphate hydrogen (NADPH) and free radical formation.

Cigarette smoking similarly contains a lot of xenobiotics which can induce free-radical production and lipid peroxidation [4].

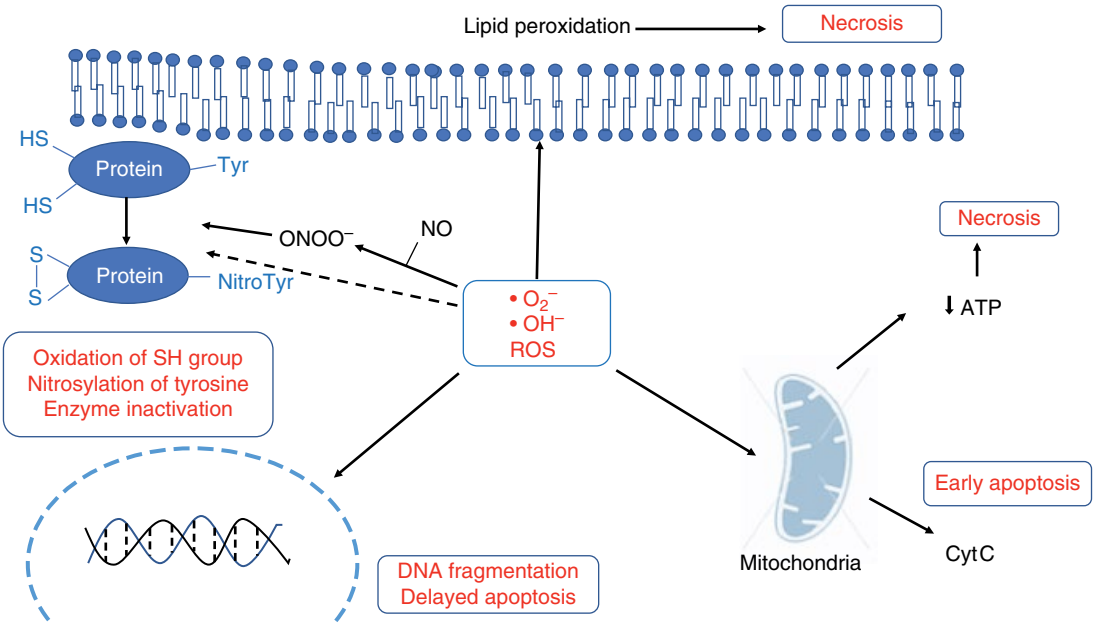

Figure 57.1 Intracellular free radicals can damage plasma membrane by lipid peroxidation. Mitochondria, which are the source of oxidative stress, get damaged which induces apoptosis by cytochrome c. Nitrosylation and oxidation of enzymes may result in their inactivation. Nuclear DNA may get fragmented inducing apoptotic pathways. ROS: reactive oxygen species.

Antioxidants

Antioxidants are substances that when present in low concentration compared to those of an oxidizable substrate significantly delay or inhibit oxidation of that substrate [5]. They can be classified into several groups: (i) cellular enzymes such as superoxide dismutase (SOD), glutathione peroxidase (GPx) and catalase (CAT); (ii) vitamins such as β-carotene, ascorbic acid, α-tocopherol; (iii) uric acid; and (iv) amino acids and proteins, which form complexes with transition metal ions. Cysteine is an important amino acid for the synthesis of glutathione. Methionine provides sulfur for the formation of cysteine and is thus an important dietary component for maintaining antioxidant defense. Selenium is a component of the GPx and Se-dependent enzyme thioredoxin reductase. These enzymes reduce hydrogen peroxide and lipid peroxides [6].

Primary defenses against oxidative stress include antioxidants vitamin E, vitamin C, β-carotene, glutathione, and uric acid. Second-line defense includes antioxidant scavenging enzymes that include SOD, CAT, and GPX. There exists a "redox homeostasis" within the cellular milieu and temporary exposure to ROS activate redox signaling (Fig. 57.2) [7].

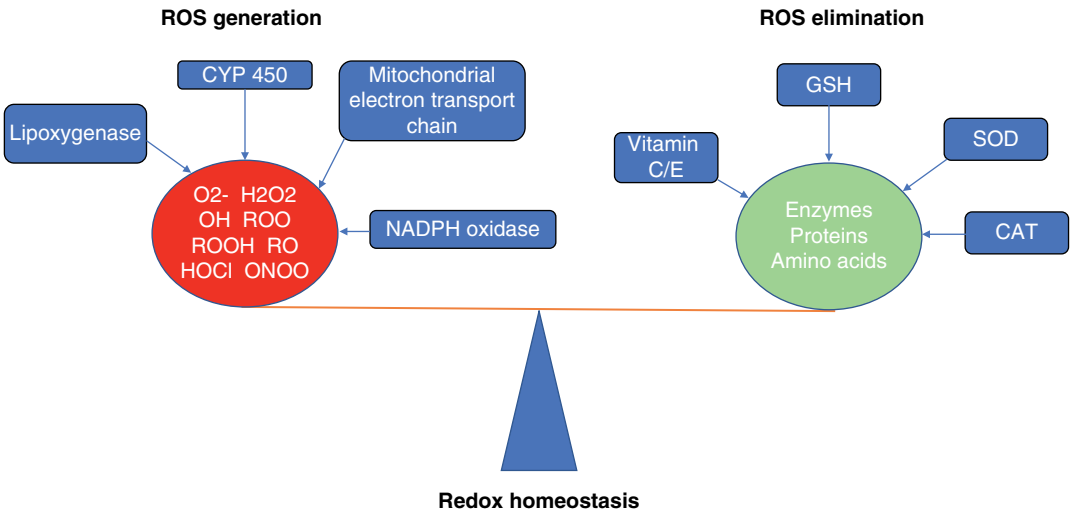

Figure 57.2 Redox homeostasis showing the balance between generation and elimination of reactive oxygen species (ROS).

Assessment of Oxidative Stress and Antioxidant Status

Oxidative Stress Markers

Measurement of thiobarbituric acid reactive substances (TBARS) is the most commonly used assay and is a marker of lipid peroxidation. Lipid peroxidation causes damage to the cell membrane. Malonaldehyde (MDA) and 4-hydroxynonenal (4-HNE) are the most important products of lipid peroxidation and can be used as markers of lipid peroxidation. Lipid peroxidation is a key step in oxidative stress mediated injury [8,9]. Some sugars may react with thiobarbituric acid resulting in assay interference [10].

Antioxidant Status Markers

Antioxidants work in tandem and complement each other. Hence, measurement of individual antioxidants may not be a direct measure of total antioxidant capacity (TAC) of the body. The ferric acid reducing ability of plasma (FRAP) measures the reducing capacity of blood from ferric to ferrous ion. FRAP is an easy and reproducible assay to measure TAC of the body [11].

Oxidative Stress in CP and its Consequences

The concept of "oxidative stress" in the pathogenesis of chronic pancreatitis can be credited to Joan M. Braganza, who proposed the hypothesis that products of hepatic detoxification may cause pancreatic diseases due to reflux of bile containing these substances into the pancreas. It was proposed that aberrant function of hepatic mixed function oxidase (MFO) may be the root cause of pancreatic diseases [12].

Rose et al. [13] first suggested that antioxidant deficiency may play a role in the pathogenesis of CP. Antioxidant deficiency was observed in patients with CP and oxidative stress was subsequently hypothesized as an important pathophysiological mechanism for the development of CP. It was supported by the observation that a high concentration of lipid-based free-radical oxidation products were detected in the serum and duodenal bile during the relatively asymptomatic phase between the recurrent attacks of pancreatitis suggesting persistent oxidative stress [14]. Three possible mechanisms were suggested: (i) CYP induction by cigarette smoking [15]; (ii) exposure to volatile petrochemical products in occupational environment [16]; and (iii) reduced dietary intakes of methionine and vitamin C in alcoholics [17,18].

Xenobiotic-mediated injury may perpetuate repeated/chronic inflammation in CP. The phase I enzymes such as CYP1A2, CYP3A, and NADPH-CYP oxidoreductase rather than phase II enzymes were found to be induced in the surgical biopsies of pancreas in a study of drug-metabolizing enzymes. Phase II enzymes facilitate removal of xenobiotics after conjugation with GSH, but phase I enzymes may produce toxic intermediates. In addition, pancreatic acinar cells showed evidence of oxidative stress [19].

ROS can lead to acinar cell death in pancreatitis. ROS is a key mediator of CCK-induced apoptosis in experimental pancreatitis. This is mediated by increasing intracellular calcium leading to release of mitochondrial cytochrome c, which activates caspases causing apoptosis [20,21]. ROS can also activate pancreatic stellate cells (PSC). PSC may also generate ROS by NADPH oxidase, which mediates activation of PSC [22].

Evidence for Oxidative Stress and Total Antioxidant Status in CP

Lipid peroxide activity was studied by Basso et al. [23] in 49 patients with CP, 28 patients with pancreatic cancer, 40 controls, and 53 patients with extrapancreatic diseases. It was observed that lipid peroxide activity was increased in patients with CP during disease relapse and correlated with the degree of inflammation.

Szuster-Ciesielska et al. [24], studied the ability of blood neutrophils to produce superoxide anion and hydrogen peroxide spontaneously and after stimulation and showed that the resting production of these free radicals was significantly higher in patients with pancreatitis compared with controls. Superoxide dismutase and catalase activities were greater in patients with alcoholic pancreatitis than controls.

Patients with CP and pancreatic cancer had higher levels of Cu/Zn superoxide dismutase in the pancreatic juices collected endoscopically compared with controls. Immunohistochemical studies of Cu/ZN-SOD in pancreatic tissue showed localization to ductal cells, islet cells, and centro-acinar cells but to a much lesser extent to acinar cells [25].

Schoenberg et al. [26] studied lipid peroxidation products in the tissue and serum of patients suffering from acute ($n = 9$) and chronic pancreatitis ($n = 11$). In patients with CP, the products of lipid peroxidation such as conjugated dienes and malonaldehyde were higher in pancreatic tissue compared to controls (organ donor). Reduced glutathione was significantly decreased suggesting oxidative stress. Increased levels of tissue lipid peroxidation products and altered glutathione

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. metabolism suggested ongoing peroxidation of lipids due to an enhanced generation of oxygen radicals.

Patients with alcoholic CP have low blood levels of many antioxidant factors despite adequate oral intake. In a study, serum levels of Vitamin A, Vitamin E, selenium, and glutathione peroxidase level were significantly lower compared to healthy controls despite no dietary differences in these micro-nutrients. The study hypothesized that such deficiency was probably due to pancreatic insufficiency and increased requirement due to oxidative stress [27].

In another study, Mathew et al. [28] evaluated antioxidants in patients with hereditary CP. Antioxidants levels in four groups were compared: hereditary CP, kindred but no pancreatitis, CP due to other etiology, and controls. Hereditary CP patients had lower antioxidant levels. Their kindred had higher vitamin E and selenium levels, which might have prevented them from having pancreatitis despite low glutathione peroxidase levels. Hence, the authors hypothesized that supplementation with vitamin E and selenium might be a good therapeutic option to decrease the frequency of pancreatitis in patients with CP.

Patients with CP in tropical areas had earlier onset of pancreatitis. In a study, Braganza et al. [29] showed that the bioavailability of beta-carotene and ascorbic acid was lower in tropical areas compared to temperate zones. The culinary practice that erodes bioavailability of these two antioxidants might have predisposed to pancreatic oxidative stress and earlier presentation of CP in tropical countries compared to temperate countries.

Whether presence of diabetes significantly modifies oxidative status in patients with CP was evaluated in another study. CP patients with or without diabetes were compared with type 1 diabetes and healthy controls for oxidant and antioxidant status as well as LDL oxidation status. Antioxidant status was altered in patients with CP particularly in those with diabetes. In these patients, vitamin E deficiency and elevated plasma glucose level were associated with significantly higher LDL oxidizability predisposing to atherosclerosis [9].

Uden et al. [17] found significantly low antioxidant levels of selenium, vitamin C, and vitamin E compared to controls in patients with idiopathic CP and suggested that selenium supplementation might be beneficial.

The question whether oxidative stress played any role in the progression of disease from recurrent acute to chronic pancreatitis was addressed in a recent study by Bopanna et al. [30]. The study included patients with idiopathic recurrent acute pancreatitis both in the acute phase and the quiescent phase to evaluate oxidative stress and found that patients had oxidative stress during the acute phase of illness and antioxidants levels were reduced. Taken together, the findings suggested that oxidative stress was associated with recurrent attacks of pancreatitis and might be contributing to the progression of recurrent acute pancreatitis to CP.

Hence, most studies have shown the presence of oxidative stress and decreased antioxidant levels in patients with CP. The low antioxidant levels may be due to dietary deficiency or impaired absorption resulting from pancreatic insufficiency or from increased consumption due to oxidative stress.

Role of Antioxidant Supplementation in CP

To mitigate oxidative stress and correct antioxidant deficiency, it was postulated that antioxidant supplementation might be beneficial. There are multiple randomized controlled trials (Table 57.1) and meta-analyses to address this issue.

The first RCT was conducted by Uden et al. [31]. It was a double-blind placebo-controlled crossover RCT. Twenty-three patients were recruited of whom only 20 were included in the final analysis (7 had alcoholic CP, 8 had idiopathic CP, and 5 had recurrent acute pancreatitis). One arm was given combination antioxidants (daily 600 µg selenium, 0.54 gm ascorbic acid, 9000 IU β-carotene, 270 IU α-tocopherol, and 2 gm methionine) and the other arm was given placebo. Total duration of treatment was 20 weeks with crossover at 10 weeks. Six patients on placebo had recurrent attacks compared to none in the antioxidant arm. The authors concluded that active treatment was associated with clinical improvement over and above placebo effect.

Banks et al. [32] subsequently studied the antioxidant allopurinol in patients with painful CP and compared it with placebo. There was no decrease in visual analog scale (VAS) score or McGill score with the intervention though the study was limited by a small sample size of only 16 patients. Bilton et al. [33] also failed to show any improvement in VAS score in a double-blind placebo-controlled RCT of combination antioxidants (daily 800 mg SAMe, 600 µg selenium, and 9000 IU β-carotene) compared to placebo.

Curcumin supplementation for 6 weeks did not show any improvement in VAS score compared to placebo in an RCT. Though the study showed improvement in GSH level in red blood cells and decrease in MDA levels, there was no improvement in pain [34].

In a double-blind placebo-controlled crossover RCT, 36 patients with CP were randomized to receive combination antioxidants (4 times daily 75 µg selenium, 3 mg β-carotene, 47 mg d-α-tocopherol, 150 mg ascorbic acid, and 400 mg methionine) or placebo for 20 weeks with crossover at 10 weeks. There was significant improvement in pain component of SF 36 score with the combination antioxidant therapy [35].

Table 57.1 Summary of trials of antioxidant supplementation in chronic pancreatitis.

Author	Type of study	*N*	Intervention	Outcome measures	Results	Remarks
Uden 1990	Double-blind placebo-controlled crossover RCT	23	Combination antioxidants (daily 600 µg selenium, 0.54 gm ascorbic acid, 9000 IU β-carotene, 270 IU α-tocopherol, and 2 gm methionine) vs. placebo Duration: 20 weeks, no washout period	• VAS • McGill pain score • Descriptive pain score	• 1.01 (0.16–4.26) vs. 1.88 (0.22–5.76), NS • No significant difference • No clear difference • 6 patients in placebo had attack compared to none with intervention	Low risk of bias
Salim 1991	3 armed, parallel, double-blind, placebo-controlled RCT	78 (25 vs. 26 vs. 27)	4 times daily 50 mg allopurinol vs. 500 mg dimethyl sulfoxide vs. placebo Duration: up to 24 hours pain-free (mean = 45 hours)	• Number of pain-free patients • Discharge days	• 13 vs. 12 vs. 4 • 3 days vs. 3 days vs. 5 days	Unclear risk of bias
Bilton 1994a	Double-blind placebo-controlled crossover RCT	30	3 daily doses of 800 mg S-adenosyl methionine (SAMe) vs. placebo Duration: 20 weeks (no washout)	• VAS	No difference	Data not shown
Bilton 1994b	Double-blind placebo-controlled crossover RCT	14	Combination antioxidants (daily 800 mg SAMe, 600 µg selenium, and 9000 IU β-carotene) vs. placebo	VAS	No difference	Data not shown
Banks 1997	Double-blind placebo-controlled crossover RCT	16	Allopurinol 300 mg/d vs. identical placebo Duration: 10 weeks with 2 weeks washout after initial 4 weeks	• VAS score (0–100): difference in mean decrease from baseline • McGill's score (0–45): difference in mean decrease	• 2.8, $P = 0.24$ • -0.3, $P = 0.75$	Low risk of bias
Nandi 2002	Parallel placebo-controlled RCT	25	Combination of antioxidants (daily 600 µg selenium, 0.54 gm ascorbic acid, 9000 IU β-carotene, 270 IU α-tocopherol, and 2 gm methionine) vs. placebo Duration: 6 months	• Pain score (12 points) • Pain-free days/mo	• 1.25 vs. 3.62, NS • 3.75 vs. 4.12, NS	Unclear risk of bias
Durga Prasad 2005	Parallel single-blind placebo-controlled RCT	20	Combination antioxidants (3 times daily 500 mg curcumin and 5 mg piperine) vs. placebo Duration: 6 weeks	VAS score (after intervention)	5.81 (0.74) vs. 6.57 (0.74), NS	High risk of bias

Table 57.2 Summary of meta-analyses on antioxidant supplementation in chronic pancreatitis.

Author	Study types included	Number of studies	Outcome measures	Conclusion
Ali et al. 2014 Cochrane systemic review	RCT	12 (585 participants)	Pain complaints pre- and post-intervention	Antioxidants can reduce pain slightly in CP. Adverse events in 1 in 6 patients may prevent use
Zhou et al. 2014	RCT	8 (573 participants)	Pain relief	Antioxidant administration effective in relieving pain
Rustagi et al. 2015	RCT	8 (446 participants)	Pain reduction	Benefit of antioxidant therapy for pain reduction (RR: 0.73; 95% CI: 0.58–0.91)
Mohta et al. 2020	RCT	4 (352 participants)	Pain relief Quality of life	No significant pain reduction or change in quality of life

The limitations of these studies were a small sample size, inclusion of predominantly alcoholic CP, nonstandardized quantification of pain, and short duration of antioxidant supplementation.

Bhardwaj et al. conducted a double-blind placebo-controlled RCT to study the role of antioxidant supplementation in patients with both alcohol-related and idiopathic CP. A total of 127 patients with CP (age 30.5 ± 10.5 years, 32 alcohol-related and 95 with idiopathic CP) were randomized to receive either antioxidants ($n = 56$; daily 0.54 gm ascorbic acid, 9000 IU β-carotene, 270 IU α-tocopherol, 600 µg selenium, and 2 gm methionine) or placebo ($n = 71$), for 6 months. There was a significant reduction in number of painful days per month in the antioxidant group (7.37 [6.75] vs. 3.21 [3.99], $P < 0.001$). Twenty-three out of 71 patients were pain-free in the antioxidant group compared to 7 out of 56 in placebo ($P = 0.009$). The reduction in levels of TBARS and increase in levels of FRAP were also significantly higher in the antioxidant group, which was commensurate with the clinical observation [36].

Another trial randomized 70 patients with CP to receive either combination antioxidant, ($n = 33$; 38.5 mg selenium, 113.4 mg d-tocopherol acetate, 126.3 mg ascorbic acid, and 480 mg l-methionine) or placebo ($n = 37$) for 6 months [37]. The study did not find improvement in VAS score or number of pain-free patients with the antioxidant therapy. However, there were several limitations of the study which prevented its generalizability: all the patients were receiving a mean of 85 mg/day opioids suggesting chronic neuropathic pain, more than half of patients had failed prior medical or surgical therapy suggesting that they have a severe unresponsive disease, and they continued to drink alcohol and smoke during the study period [38].

One study evaluated the combined role of antioxidants and pregabalin in patients with recurrence of pain following surgical/endoscopic therapy and showed that the combination therapy significantly reduced pain [39].

Four meta-analyses [40–43] have been done to date to study the role of antioxidant supplementation in pain relief in CP (Table 57.2). Three out of four meta-analyses have shown benefit with antioxidant therapy. In the Cochrane systemic review and meta-analysis [40], which evaluated 12 RCTs including 585 participants, there was a slight reduction in pain with the antioxidant therapy. It showed that adverse events might prevent use of antioxidants in one out of six patients. Effects on other outcomes such as use of analgesics, exacerbation of pancreatitis, and quality of life remained uncertain.

Conclusion

Pain is the predominant symptom in patients with chronic pancreatitis. There is compelling evidence that oxidative stress is involved in the pathogenesis of CP. Patients with CP are deficient in antioxidants due to impaired absorption and increased demand. Supplementation with antioxidants is beneficial in reducing pain in patients with CP.

Introduction

Pancreatitis is a complex, multifactorial pathology that involves the pancreatic gland. Two main types of pancreatitis are known: acute and chronic pancreatitis. Chronic pancreatitis (CP) is the step following an acute injury, which determines irreversible modifications to parenchymal structure, leading in turn to exocrine and endocrine insufficiency. To sum up this concept, a definition was coined: "chronic pancreatitis is a pathologic fibro-inflammatory syndrome of the pancreas in individuals with genetic, environmental and/or other risk factors who develop persistent pathologic responses to parenchymal injury or stress" [1]. It is estimated that incidence of newly diagnosed CP ranges from 4 to 12 per 100,000 persons per year; male:female ratio is 1.5:1, and age at diagnosis is 35–55 years [2,3]. Alcohol abuse is a primary cause of pancreatitis (about 70% of cases). A miscellanea of other causes, among them cystic fibrosis tumor, pancreatic resection, congenital abnormalities, autoimmune, and genetic, are responsible for 10% of pancreatitis, while the etiology remains unclear for the remaining 20% [4,5]. Chronic inflammation of the pancreas is characterized by a series of histologic modifications, according to the "two-hit model": acute inflammation, due to the various etiologies mentioned above, determines injury to the pancreatic parenchyma. Sustained inflammation of the pancreas leads to activation of a profibrotic cascade, which replaces endocrine and exocrine cells and determines loss of function [6]. The clinical signs and symptoms of acute pancreatitis, in decreasing order of frequency, are: abdominal pain, weight loss, steatorrhea, malabsorption, history of alcohol abuse, history of recurrent pancreatitis. Pain is the first symptom, which is reported by patients in almost 75% of cases and it persists in 85–97% of cases [7]. Three typical pain profiles have been described: (i) acute intense pain associated with repeated episodes of acute pancreatitis (acinar necrosis) in the early stage; (ii) a spontaneous lasting pain relief in association with severe pancreatic dysfunction in the late stage of uncomplicated chronic pancreatitis; and (iii) a persistent severe pain (or frequent recurrent episodes of pain) usually in association with local complications such as pseudocysts, ductal hypertension, or extrapancreatic complications such as partial obstruction of the common bile duct, peptic ulcer, and opiate addiction [8]. Timing of evolution of pain and of the pathology is impossible to predict at the time of onset [9], but it is calculated that it takes about 18 years from onset of the pathology to complete destruction of pancreatic parenchyma (burnout), which leads to a paradoxical decrease of clinical pain [7].

The main difficulty in diagnosing chronic pancreatic pain is the assessment of its entity. With the aim of providing a standardized measure of this symptom, several instruments have been validated: one-dimensional scales that use numeric (usually 0 to 10), verbal, or visual descriptors to quantify pain or the degree of pain relief [8]; and multidimensional scales that measure aspects of pain (intensity, nature and location, impact of paint on mood or activity level) [10].

Figure 58.1 presents a graphical synthesis from suspect clinical findings to proposed treatment.

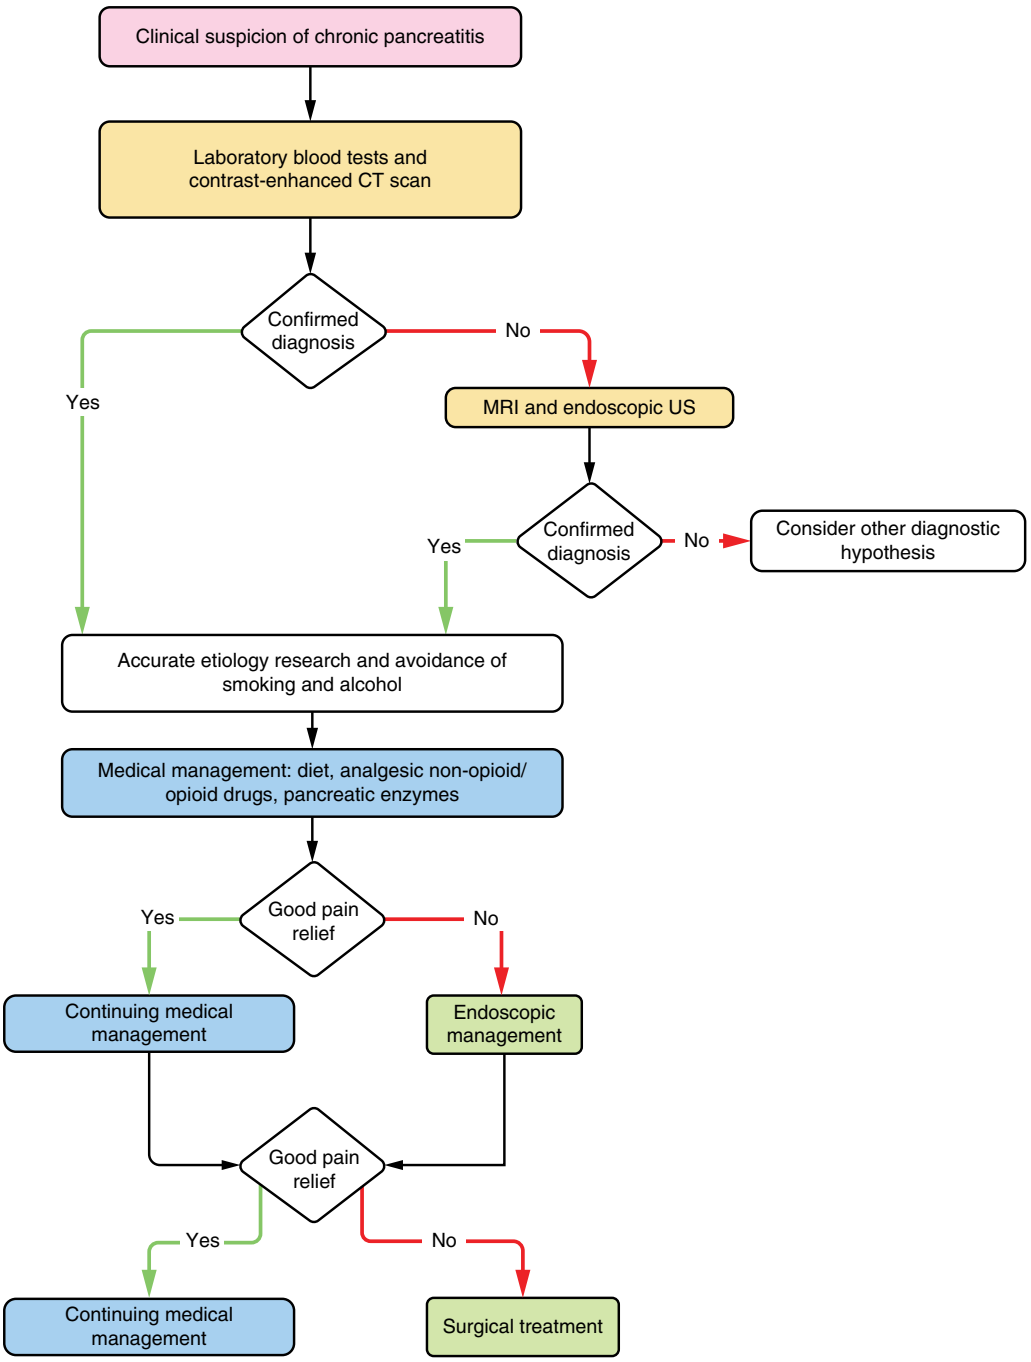

Figure 58.1 Algorithm for chronic pancreatitis.

Pathogenesis

Pathogenesis of pancreatic pain is still incompletely understood. First theories emerged at the beginning of the nineteenth century during comparative studies in relation to stones in salivary and biliary ducts [11]. Three levels of pain interest are proposed: extrapancreatic, intrapancreatic, and central.

Extrapancreatic Pain

Bile duct and duodenal stenosis due to extensive pancreatic fibrosis and inflammation have been considered extrapancreatic causes of pain [12]. Becker and Mischke described a pathologic condition named "groove pancreatitis" in 19.5% of 600 patients with CP [13]. This is characterized by the formation of a scar plate between the head of the pancreas and the duodenum. The scar

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. complications are determined by the topography: disturbance in the motility of the duodenum, stenosis of the duodenum, and tubular stenosis of the common bile duct, occasionally leading to obstructive jaundice. These alterations have been suggested to be responsible for several symptoms present in CP and for postprandial pain due to compression of nerves and ganglia located between the pancreatic head and the duodenum [14].

Intrapancreatic Pain

Authors have identified several possible causes of intrapancreatic (or pancreatic) pain that can act together: ductal hypertension, parenchymal hypertension, parenchymal ischemia, pseudocysts, autoimmune disease, and neural remodeling.

Ductal Hypertension

Many investigators have related the origin of pain to increased pressure in pancreatic ducts due to strictures or stones [15]. It is calculated that normal pressure in the main pancreatic duct is between 7 and 15 mmHg, while in cases of CP, ductal pressure increases to 20–80 mmHg [16]. In ductal hypertension, alcohol plays an important etiopathogenetic role. Alcohol promotes lithiasis, which, in turn, promotes inflammation, which leads to strictures [17]. The "ductal hypertension hypothesis" as an explanation for pain in CP is supported by observations that decompression of a dilated pancreatic duct or pseudocyst frequently relieves pain [18]. Clinical trials have shown that relief from pain might be achieved by eliminating stones and strictures (surgery) or by reducing secretion (octreotide and somatostatine) [19]; however, it has been estimated that around 30% of the patients treated with decompressive surgery experience recurrent attacks of pain [20]. Conversely, some authors found no relationship between pain score and pancreatic pressure, although the intrapancreatic pressure was positively correlated with ductal changes, and they concluded that pancreatic parenchymal pressure is not closely related to pain in CP [21].

Interstitial Hypertension

According to this theory, pain is induced when increased pancreatic ductal and parenchymal pressure produce a compartment syndrome that causes ischemia [22]. This hypothesis is supported by experimental studies [23] which show increased interstitial pressure correlates with decreased blood flow in a feline model of CP. These abnormalities were reversed by surgical incision of the gland and draining the pancreatic duct, but were affected minimally by stenting the pancreatic duct. This would suggest that incision of the gland may be more important in relieving pain than ductal drainage. In addition, different studies [24,25] revealed that the degree of pancreatic fibrosis has no significant influence on pain generation since no correlation between the degree of fibrosis and intensity of pain could be demonstrated.

Ischemia

According to this theory, vascular resistance is augmented due to fibrosis, which may lead to hypoperfusion of the parenchyma. In a feline study, it was demonstrated that pancreatic perfusion in case of chronic inflammation is decreased by 40% [26].

Pseudocysts

Pseudocysts can cause intense pain in patients with CP. In the majority of cases (60%) treatment with octreotide results in a reduction in size and the eventual disappearance of the pseudocysts together with reduction of pain [27]. Enlargement of pseudocysts, causing compression of adjacent structures, might be a mechanism for pain generation.

Autoimmune Disease

Several authors have described patients with CP associated with autoimmune diseases. Sarles et al. [28] described a type of CP that might be caused by an autoimmune mechanism and termed it "primary inflammatory sclerosis of the pancreas." Yoshida and colleagues [29] reported a similar case and proposed that pancreatitis with these characteristics has to be considered as autoimmune pancreatitis. Current accepted terminology for this condition is lymphoplasmacytic sclerosing pancreatitis or autoimmune pancreatitis [30]. Pain is often associated with this type of inflammation although the genesis of this clinical symptom has not yet been investigated.

Neural Remodeling

Neurogenic inflammation as a result of pancreatic inflammation and neural remodeling has recently been linked to both acute and chronic pancreatitis. Neurogenic inflammation encompasses a series of vascular and nonvascular inflammatory responses, triggered by the activation of primary sensory neurons (C- or Aδ-type nerve fibers) and the subsequent release of inflammatory neuropeptides, including substance P (SP) and calcitonin gene-related peptide (CGRP), and has been validated in human as well as in animal models of acute and chronic pancreatic damage [31,32]. Pancreatic and central changes can be distinguished.

Pancreatic Changes

Keith et al. suggested initially that neural and perineural alterations might be important in pain pathogenesis in CP [33]. They concluded that pain severity correlated

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. with the duration of alcohol consumption, pancreatic calcification, and the percentage of eosinophils in perineural inflammatory cell infiltrates, but not with duct dilatation. A subsequent study demonstrated an increase in both number and diameter of pancreatic nerve fibers in the course of CP [34]. In tissue specimens from patients with chronic pancreatitis, foci of chronic inflammatory cells were often found surrounding pancreatic nerves (called pancreatic neuritis), which by electron microscopic analysis exhibit a damaged perineurium and invasion by lymphocytes. The changed pattern of intrinsic and possibly extrinsic innervation of the pancreas in CP suggested that there could be an upregulation of neuropeptides that usually populate those enlarged nerves. In fact, a further study [35] showed that there were striking changes in peptidergic nerves in CP. The changes consisted of an intensification of immunostaining for CGRP and PS in numerous nerve fibers. Because both of these peptides are generally regarded as pain neurotransmitters, these findings provided evidence for direct involvement of pancreatic nerves in the long-lasting pain syndrome in CP. Later reports [30,36] revealed that the presence of growth-associated protein-43 (GAP-43), an established marker of neuronal plasticity, directly correlated with the pain scores in patients with CP. GAP-43 is a neuronal protein known to be involved in the development of axonal growth cones and presynaptic terminals, and mRNA and protein levels of GAP-43 are increased after neuronal lesions. In the chronically inflamed human pancreas, enzymatic and double fluorescence immunohistochemistry reveals a significant expression of GAP-43 in the majority of pancreatic nerve fibers. These immunohistochemical findings correlated with clinical and pathological findings in patients with CP, including the parenchyma–fibrosis ratio and the degree of perineural immune cell infiltration. Furthermore, a strong relationship with individual pain scores was present. The infiltration of pancreatic nerves by immune cells is significantly related to pain intensity, whereas pain scores do not correlate with the degree of pancreatic fibrosis or with the duration of the disease. The demonstration of a direct relationship between the degree of perineural inflammation and the clinical pain syndrome strongly supports the hypothesis of "neuroimmune interaction" as an important, if not predominant, factor in pain generation in patients with CP.

An interesting question concerns the mechanisms that contribute to the enlargement of pancreatic nerves. A recent study analyzed the expression of nerve growth factor (NGF) and one of its receptors (TrkA) in patients with CP [32]. NGF belongs to the neurotrophin family and plays a role in neuroblast proliferation and neuronal maturation, affecting neuronal phenotype and maintaining neuronal survival. NGF signaling is mediated via binding high- and low-affinity receptors. TrkA is present in dorsal root and peripheral ganglia cells of primary sensory nerves, and is involved in signal transduction of noxious stimuli and tissue injury. Inflammation results in an elevation of NGF levels in different diseases. Interestingly, NGF may itself have cytokine-like functions; it can modify mast cell, macrophage, and B-cell functions, but may also activate TrkA located on sensory and sympathetic nerve fibers innervating the site of inflammation, thus modulating neuroimmune interactions. In CP tissue samples NGF and TrkA mRNA expressions are markedly increased and enhanced in pancreatic nerves and ganglia. Comparison of the molecular findings with clinical parameters revealed a significant relationship between NGF mRNA levels and pancreatic fibrosis and acinar cell damage, and between TrkA mRNA levels and pain intensity. These findings indicate that the NGF/TrkA pathway is activated in CP and that this activation might influence nerve growth and the pain syndrome, most probably by modulating the sensitivity of NGF-independent primary sensory neurons through increasing channel and receptor expression [32]. Similar results showing positive correlation with pain intensity and frequency in patients with CP were reported for brain-derived neurotrophic factor gene expression, a member of the neurotrophin family [37]. In addition, upregulated NGF might influence the pain syndrome in CP patients by regulating transcription and synthesis of SP and CGRP, as well as through the release of histamine. The neuropeptide SP is the main tachykinin involved in neural transmission of sensory information, smooth muscle contraction, nociception, sexual behavior, and possibly wound healing and tissue regeneration [38,39]. SP has wide-ranging functional effects, including the crosstalk between nervous and immune systems by acting through its specific neurokinin-1 receptor (NK-1R). A recent report by Shrikande et al. [40] demonstrated a significant correlation between NK-1R and clinical–pathologic findings in patients with CP. In CP samples, NK-1R mRNA expression and protein were localized mainly in nerves, ganglia, blood vessels, inflammatory cells, and occasionally in fibroblasts. A significant relationship between NK-1R mRNA levels and intensity, frequency, and duration of pain in CP patients was reported. The expression of NK-1R in inflammatory cells and blood vessels also points to crosstalk between immunoreactive PS nerves and inflammatory cells and blood vessels, and further supports the existence of a neuroimmune interaction that probably influences the pain syndrome and chronic inflammatory changes in CP. In addition, a recent study demonstrated that PS mRNA expression levels were higher in CP tissues compared with controls, whereas

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. neprilysin (NEP) mRNA levels showed no significant differences between CP patients and healthy subjects. In CP patients, PS serum levels correlated with those in tissues, and after surgical resection SP serum levels were reduced compared to preoperative values. Failure of NEP to overexpress in CP tissues was associated with significant miR-128a overexpression, suggesting that in an PS/NEP-mediated pathway NEP fails to provide adequate surveillance of SP levels and this failure of NEP might be microRNA associated [41]. The exact mechanisms involved in the interaction between inflammatory cells and nerves and ganglia—neuroimmune crosstalk—are not yet fully clarified. Different cytokines have been shown to interact with SP in various paradigms for pain and inflammation. SP directly stimulates the release of interleukin 8 (IL-8) from macrophages. IL-8 release generates hyperalgesia by stimulation of postganglionic sympathetic neurons. A significant increase of IL-8 mRNA was reported in CP tissue samples [42]. IL-8 was present mainly in macrophages surrounding the enlarged pancreatic nerves, in remaining acinar cells, and often in ductal cells. IL-8 mRNA expression was positively correlated with the inflammatory score and the presence of ductal metaplasia in CP tissue samples. The reported findings in the literature on the interaction of SP and IL-8, in combination with what has been reported in CP, suggests that the increased mRNA expression of IL-8 in CP could in part be mediated by SP released from sensory pancreatic nerves. In addition, the release of IL-8 from the remaining exocrine pancreatic parenchyma suggests the fascinating hypothesis of an intrinsic maintenance of the inflammatory response after the initial damage to the pancreatic gland, thus sustaining progression and evolution of the disease. In addition, in a rat model it was found that repeated caerulein stimulation causes experimental pancreatitis that is mediated in part by stimulation of vanilloid receptor type 1 (VR1) on primary sensory neurons, resulting in endogenous SP release [43]. These results were confirmed in human pancreas [44]. In fact, an activation of the VR1 in pancreatic tissues from patients with pancreatic cancer and CP is known. This increase was correlated with pain score in those patients. The release of PS and Na+/K+-ATPase (NKA) from primary afferent (sensory) nerve endings to various stimuli is now considered to be induced by activation of the capsaicin (vanilloid) receptor (VR1).

Central Involvement

Patients with CP have lower thresholds to pain in response to deep abdominal palpation than healthy individuals (reflecting secondary referred hyperalgesia in the musculature) [45]. Furthermore, the area of referred pain is expanded in patients with CP who are subject to experimental electrical stimulation of viscera with changes in evoked potentials in the brain [46–48]; these data have also been confirmed by magnetic resonance imaging. These patients report hyposensitivity to cutaneous stimulation, probably as a result of altered descending inhibitory influences on spinal nociceptive neurons [49] and hyperalgesia to rectosigmoid stimulation, accompanied by impairment in diffuse noxious inhibitory control, a phenomenon that reflects descending central inhibition of pain, thought to be a countermeasure to noxious stimulation [50]. Central sensitization is associated with reduced efficacy of invasive endoscopic and surgical treatments directed at the pancreas [51]. In contrast to the previous sentences, many patients with continuous pain do not have structural complications or evidence of inflammation: this could be the case of a neuropathic pain [52].

Conclusion

Pain is the most frequent clinical feature in patients with chronic pancreatitis. Many components are responsible for pain at intrapancreatic, extrapancreatic, or central nervous system level, with different expression in relation to the individual patient, nociceptive level, and comorbidities. There is a complex network among neuropeptides, immune cells, cytokines, and NGF. Neuropeptides released from the enteric nervous system and their spatial relationship with inflammatory cells play a key role in pancreatic pain. A fuller knowledge of the physiopathology of pain may lead to a complete and effective medical and surgical treatment of chronic pancreatitis and its manifestations.

Pain Management in Chronic Pancreatitis

Louise Kuhlmann, Søren S. Olesen, and Asbjørn M. Drewes

Centre for Pancreatic Diseases & Mech-Sense, Department of Gastroenterology and Hepatology, Aalborg University Hospital, Aalborg, Denmark

Introduction

Abdominal pain is the most common symptom in chronic pancreatitis (CP), and it remains a clinical challenge. Pain affects about 90% of patients along the course of the disease and can present in various forms [1,2]. The classical description of pancreatic pain is a constant, dull, epigastric pain that radiates to the back and is worsened by intake of high-fat foods [3]. Intensity can present in forms ranging from a barely noticeable sensation to immense, continuous pain. Some patients experience episodes of severe abdominal pain, whereas others experience a daily aching pain that may be exacerbated by acute flares [3]. Pain pattern has traditionally been looked at as either type A pain (intermittent pain with pain-free intervals in-between) or type B pain (constant pain with or without exacerbations) as described by Ammann et al. [4], but recent research concluded that several shifts between pain patterns can occur during the course of the disease [5]. Regardless of the type of presentation, pancreatic pain highly affects quality of life and is a risk factor for hospitalizations [6,7]. In an examination of 540 American CP patients in the NAPS2 (North American Pancreatitis Study 2) cohort, most patients reported at least one hospitalization in the last year, 25% were on disability benefits, and there was no association between the duration of the disease and pain severity [1].

Pathophysiology

Pain in CP is poorly understood, and the underlying mechanisms are still debated. However, generally, it is agreed that pancreatic pain has elements of nociceptive pain, obstructive factors, and neuropathic/neuroplastic pain [3,8].

Nociception is the process whereby the sensory nervous system encodes noxious stimulations. It involves the activation of specific neural processes leading to an action potential that forwards the signal through the dorsal horn of the spinal cord and through ascending pathways to the limbic, thalamic, and cortical regions of the brain. Nociception can lead to the perception of pain, but as outlined below, pain is a subjective experience including affective and cognitive components, together with suffering and changes in behavior.

It is hypothesized that ductal and mechanical alterations can cause pain, especially ductal obstructions and local inflammatory masses. However, radiological findings are not correlated with pain severity [3,9], and postoperative long-term pain relief is dependent on many other factors [10].

The perception of pain is generally induced by tissue injury, but the neural structures can become sensitized over time. Sensitization will induce a greater neural response to noxious stimulations and increase the sensation of pain, leading to hyperalgesia. Sensitization can occur both peripherally in the primary nociceptors and centrally at the spinal level or higher levels, including the brain [11].

In CP, continuous inflammation can cause the pancreatic nerve fibers to convey signals to the brain, which is perceived as pain. The inflammation will cause the pancreatic tissue to break down, and the nerves can then be exposed to toxins and chemicals, leading to nerve hypertrophy, an increase in density, and an increased number of nerve endings [12]. These findings correlate with pain intensity and support the theory of neuropathic pain [13]. In such cases, spontaneous firing from the damaged

Companion website: www.wiley.com/go/beger/thepancreas4e

nerves and central sensitization, and lack of normal inhibition can amplify the pain.

Pancreatic nociception seems to be affected significantly in CP, where increased excitability is linked to an upregulation of several molecules, including the vanilloid receptor TRPV1, calcitonin gene-related peptide (CGRP), nerve growth factor (NGF), and the protease-activated receptor 2 (PAR-2) [8]. This upregulation is believed to drive neural sensitization, starting peripherally and progressing centrally.

Pain in CP can also be secondary, related to complications of CP and treatment [14]. For example, CP patients are at increased risk of developing peptic ulcers and bacterial overgrowth in the small intestines. Furthermore, the analgesic treatment, especially opioid treatment, may result in severe side effects that can increase pain, including constipation and opioid-induced hyperalgesia. All of these complications need to be addressed appropriately to reduce pain.

Pancreatic pain does, however, comprise more than just nociception and pain intensity. Cognitive dimensions of pain include how the patient perceives him/herself in pain and predispositions for coping with pain, including temper and personality traits. Affective dimensions include depression and anxiety, which affect pain processing and the perception of pain. Finally, behavioral dimensions, such as grimacing, crying, and limping, can induce empathy in relatives and secondarily increase pain behavior. However, this negative spiral can ultimately also increase pain perception [15].

This multifactorial nature needs to be taken into account when managing pain in CP. However, patients differ with respect to pathophysiology, genetic and social factors, etc., and treatment should be tailored to the individual rather than a one-size-fits-all approach [16].

Pain Assessment

The clinician should always start with a thorough pain assessment to guide treatment. Pain intensity, pain pattern, factors that provoke or worsen pain can be important when determining which mechanisms are involved in the development of pain. In addition, this information can be used when evaluating whether the pain is nociceptive or neuropathic. Evaluation should include questions on pain intensity and characteristic features, pain interference on physical and emotional functioning, and quality of life assessment [17]. For details, the reader is referred to a recent guideline paper in pain assessment of CP [14]. Unfortunately, pain assessment tools developed specifically for CP have proven to be either dominated by unidimensionality, lack of validity and reliability testing, or poor coverage [18]. For example, the Izbicki pain score developed for CP has been used in several studies, although it has never been formally validated [19,20]. Other pain questionnaires such as the Brief Pain Inventory have also been used extensively in CP and it is validated for nonmalignant pain; however, it lacks focus on features characteristic of pancreatic pain [21]. As a result, the COMprehensive Pain Assessment Tool (COMPAT) has been developed to include all core dimensions of pain and aspects specific to CP [22]. In addition, a short-form was recently developed to increase the clinical usability, comprising five pain dimensions to characterize pancreatic pain, including pain severity, pain pattern, factors provoking pain, qualitative pain assessment, and spreading pain. It has been validated and tested to be reliable in three centers in Denmark, New Zealand, and the United States [23].

As many pain assessment questionnaires do not include quality of life assessment, they can be accompanied by questionnaires such as, for example, the European Organisation for Research and Treatment of Cancer (EORTC) questionnaire for quality of life assessment [24].

Besides pain assessment tools, quantitative sensory testing (QST) has been examined as a diagnostic test for assessing somatosensory function in CP. QST is a method for determining how patients respond to painful stimulations. For example, a QST technique called the Pancreatic QST (P-QST) protocol uses bedside pressure testing, repetitive stimulations, and conditioned pain modulation testing to evaluate the nociceptive responses indirectly [25]. Studies using P-QST have phenotyped patients based on pain patterns and correlate increasing widespread hypersensitivity with pain intensity, pain interference, and quality of life [26]. In addition, neurophysiological examinations, including P-QST, can be used to guide treatment according to the presence of segmental hyperalgesia and deficient descending pain inhibition [27]. However, these methods are only available in the most advanced laboratories and are still considered research tools.

Noninterventional Pain Treatment

Pain management should start with optimizing lifestyle factors. Alcohol consumption is a significant risk factor for the development of acute-in-chronic pancreatitis. It has also been linked to the occurrence of severe pain [9]. Likewise, smoking is related to pancreatic pain as there is an increased risk of pain with an increasing number of daily cigarettes [9]. Therefore, abstinence from alcohol and smoking is an important part of hindering the progression of chronic pain and acute flares into chronic pain. It can be supported

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with medications for alcohol dependence, such as naltrexone, nicotine substitution, cognitive therapy, or mindfulness-based therapy [27]. However, even in abstinence from alcohol and smoking, the pain often persists.

Pain treatment should be managed in an interdisciplinary fashion, starting with an open discussion on treatment goals. An alignment of expectations is important, as some patients might expect complete resolution of pain, which is seldom achievable. A psychological evaluation is also essential, as comorbid depression and anxiety can worsen the sensation of pain as pain, anxiety, and depression are neuroanatomically and neurochemically linked [28]. Cognitive therapy can also be used to improve both affective mood disorders and improve pain-coping [29].

Neuromodulation has also been used successfully in treating pancreatic pain by modulating brain plasticity where mechanisms such as hyperpolarization, activation of endogenous opioids, and descending inhibition may also play a role [27,30]. It can suppress activity or promote the facilitation of the targeted area, but high-quality randomized controlled studies (RCT) are lacking. A small RCT showed that acupuncture was beneficial in CP, but the effect is short-lasting [31]. Pilot studies have shown an effect of transcranial magnetic stimulations and spinal cord stimulation, but studies have lacked a valid placebo arm and as such are subject to major bias [32].

Endoscopic and Surgical Pain Treatment

Endoscopic and surgical pain treatment is based on the rationale that pain originates from the pancreas's structural changes, such as main duct obstruction due to strictures or stones or inflammatory masses in the pancreas. Endoscopic treatment is used in the case of obstruction of the main pancreatic duct, where endoscopic retrograde cholangiopancreatography (ERCP) procedures can maintain drainage from the main pancreatic duct by pancreatic papillotomy, by extraction of pancreatic stones, or temporary stent placement [33]. However, the "plumbing theory" where ductal obstruction is the main cause of pancreatic pain is still debated. Although studies on endoscopic treatments have shown significant improvement in pain intensity in most patients, the studies are biased by several factors, including patient selection, short follow-up period, poor pain assessment methodology, and especially lack of sham control [32]. To circumvent these biases, an ongoing RCT (SCHOKE trial) randomizes patients to either active or sham extracorporeal shock-wave lithotripsy and endoscopic treatment, and currently, 50 patients are enrolled [34].

In randomized studies, surgery has proven to be superior to endoscopic treatment [20]. Surgical procedures include resection, either partial or total pancreatectomy, surgical drainage, and combinations. The argument for surgical treatment is that eliminating the source of the nociceptive pain could result in decreased firing from primary afferents and lead to decreased pain [32]. Total pancreatectomy with islet cell transplantation has gained increasing popularity but carries the risk of neuropathic pain development. Furthermore, metabolic consequences can be severe, and technical challenges remain an obstacle [11]. As studies with sham interventions are not possible with pancreatic surgery, controlled studies where patients are followed strictly for several years after surgery are needed, which may identify the role of surgery in CP [32]. However, most series have shown that a significant proportion of the patients still suffer from pain, and therefore pharmacological management is still needed.

The rationale for surgery is also applied when using neuroablative procedures to treat pain. This argument is supported by the fact that local treatments such as neural blocks can alleviate pain in peripheral nerve injury [35]. However, although neural blocks can initially affect pain intensity, studies show that they do not reduce the risk of developing allodynia or hyperalgesia [36], and nerve destruction may, in the long run, worsen neuropathy, and hence pain [30].

Pharmacological Pain Management

Simple analgesics are recommended as the first line of treatment in painful CP, especially paracetamol/acetaminophen. Nonsteroidal anti-inflammatory drugs (NSAID) can be used in selected cases but are of limited value due to gastrointestinal toxicity and CP patients' predisposition for peptic ulcers [27].

Second to simple analgesics is adjuvant therapy consisting mainly of anticonvulsants, antidepressants, and anxiolytics. In the anticonvulsive drug group, only pregabalin has been evaluated in RCT in CP and proven to provide moderate pain relief [37,38]. It has also been shown that pregabalin has inhibitory effects on central sensitization by reducing spreading hyperalgesia [39]. In addition, randomized controlled studies have shown that segmental hyperalgesia is predictive of the analgesic effect of pregabalin in CP [40]. Pregabalin is licensed for neuropathic pain and fibromyalgia but has also been used in other painful conditions with good results [41].

Antidepressants have never been examined as analgesic treatment in CP patients. However, as the noradrenergic system plays an important role in endogenous pain

modulation and antidepressants have proven effective in neuropathic pain [42], the effects may be transferable. It can also be questioned whether RCT in CP patients are needed for all analgesics. Although these patients have many specific features, there is evidence that treatment is likely to be based on the level of the individual rather than at the level of the disease [43]. Hence, data from studies in other pain patients can likely be extrapolated to CP. For example, Arendt-Nielsen and colleagues have shown that the function of the endogenous pain modulatory system predicts the analgesic effect of duloxetine in diabetic neuropathy, and other types of tricyclic antidepressants have been shown to improve the ability to modulate pain [44]. In addition, antidepressants can also be used to treat comorbid depression and anxiety, as the involvement of norepinephrine and serotonin in these diseases can affect pain processing and increase pain sensation.

Although pain management with simple analgesics and adjuvants is preferable, many patients need opioids to dampen their pain. It is necessary to closely monitor patients on opioid treatment, as adverse effects are common and include symptoms such as constipation, nausea, and opioid-induced hyperalgesia, which significantly affect the quality of life; for details, see [45,46]. Furthermore, it is estimated that only about 25% of CP patients benefit from opioid treatment, and it is necessary to evaluate treatment effects often [27]. Tramadol possesses a weak opioid agonist activity and affects the serotonin- and norepinephrine uptake [47], thereby having a dual-action effect. It is shown to be superior in South African CP patients and has fewer gastrointestinal side effects [48]. However, the results have not been validated in other ethnicities.

In general, the problem with analgesics is not the efficacy but the side effects. It is outside the scope of this chapter to describe the balance between effects and side effects and how to balance between them to the benefit of the patients, but the reader is referred to [49].

In Figure 59.1, a proposal for noninvasive treatment of pain in CP is shown.

Conclusion

Pain management remains a challenging and frustrating part of caring for patients with CP, as many issues remain unsolved.

Treatment has to be tailored to the individual, and successful pain management begins with good communication, where it is important to agree upon treatment goals early in the process. The analgesic strategy is multimodal and may include invasive treatments, medical treatments, and adjuvant treatments, bearing in mind that pain in CP is a combination of nociceptive and neuropathic/neuroplastic pain.

Adjunctive Therapy in Chronic Pancreatitis

Anna Evans Phillips MD, MS

Division of Gastroenterology, Hepatology and Nutrition, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

Introduction

Chronic pancreatitis (CP) is a progressive fibro-inflammatory disease of the pancreas for which there is no cure. Therapies in CP are directed at managing symptoms of the disease, mainly the dominant symptom of abdominal pain. Patients with evidence of pancreatic ductal obstruction are often managed with endoscopic or surgical therapy to relieve obstruction in addition to analgesia, whereas patients without clear signs of ductal obstruction are managed medically. The foundation of medical management consists of analgesic therapy, including both opioids and non-opioid analgesics. Adjunctive therapies are used to address pain by targeting mechanisms of pain that differ from traditional analgesia, as well as treating concomitant affective disorders, digestive disorders, and malnutrition. Pain treatment studies in CP are difficult to compare as endpoints vary widely between studies; however, the clinical need for pain treatment in this population persists and requires creativity and open-mindedness on the part of healthcare providers [1]. This chapter will review adjunctive therapies in CP, which are meant to serve as complementary therapies addressing pain or CP sequelae that are inadequately treated by traditional analgesia or interventions.

Therapies for Affective Disorders

Pain-related factors in CP including anxiety and depression can overlap and have a cumulatively detrimental effect on patients with CP [2]. Affective psychiatric disorders including anxiety and depression are highly prevalent in patients with CP, and frequently coexist [3]. In a cross-sectional analysis of an international cohort of CP patients, the prevalence of anxiety or depression symptoms was seen to be 46.8% and 38.6%, respectively, and their presence was associated with increased severity of pain and interference of pain with daily living [3]. The presence of depression in this study was independently associated with decreased quality of life, further highlighting the impact that psychiatric comorbidity can have in this patient population [3]. Assessment for and treatment of affective disorders concomitant with CP should be a high priority in clinical practice and symptoms can be detected effectively with questionnaire screening instruments.

Antidepressant Medications

Medical therapy for affective disorders including tricyclic antidepressants (TCA), selective serotonin uptake inhibitors (SSRI), and serotonin noradrenergic reuptake inhibitors (SNRI) have been recommended by clinical guidelines for treatment of painful CP as part of a multifaceted approach to therapy due to their analgesic effects (SNRI and TCA) and effect on concomitant depression (all three) [1]. Although they may be used in clinical practice, there is little data on the prevalence of their use or their effects in this population. The North American Pancreatitis Study 2 (NAPS2) group assessed the association between constant severe pain and genetic loci for depression and noted that 56% of that population self-reported taking an SSRI when asked for current medications [4]. There is much evidence for neuropathy in CP [5]. Multiple studies have been conducted to assess the efficacy of duloxetine, an SNRI, at treating neuropathic pain in diabetic neuropathy, fibromyalgia, and pain associated with depression, prompting a Cochrane review in 2009 and subsequent update in 2014 [6,7]. Together, the studies showed that duloxetine is effective

in reducing pain in diabetic neuropathy, as well as for pain symptoms of depression. The direct analgesic effect of duloxetine is considered to be independent of the drug's effect on depression symptoms [8], making it particularly relevant in patients with painful CP and concomitant depression. Studies in other chronic pain conditions have shown antidepressant medications broadly to have varying degrees of direct analgesia, with SSRI medications being the least analgesic but having a more acceptable tolerance profile than others [9]. While these results may be extrapolated to subgroups within the CP population, it is noted that no clinical trials have evaluated the effect of SSRI or other antidepressant medications in CP patients specifically.

Psychosocial Therapies

When regarded through the lens of the biopsychosocial model of illness, painful CP is understood as a complex phenomenon where pain, quality of life, stigma, self-blame, and addictive behaviors (for a subset of patients) impact and often exacerbate one another [10]. Psychologic therapies including mindfulness therapy and cognitive behavioral therapy are important tools to impact these forces individually. Combining any such therapies with interventions intended to address addictive behaviors including alcohol-, tobacco-, or opioid-use disorders is a priority in this population as the first two are independent risk factors for progression of CP and all can exacerbate or amplify the pain experience.

Mindfulness therapy, a talk therapy often linked to Buddhism, encourages patients to focus nonjudgmentally on the present lived experience and teaches coping mechanisms for dealing with challenges including stress and pain. In a pilot study of 10 CP patients with pain compared with 5 healthy controls, a 28-day telephone-based mindfulness therapy intervention was completed, showing improvement in social aspects of quality of life as measured by the SF-36 [11]. While there was no significant improvement in physical quality of life, and the study was limited by small sample size and a broad definition of CP, the effort did establish feasibility of such an intervention and illustrates the potential impact this could have for CP patients suffering from poor quality of life.

Cognitive behavioral therapy (CBT), a psychosocial intervention aiming to challenge cognitive distortions and improve emotional regulation and coping, has also previously been tested in an internet-based randomized, controlled pilot trial of 30 subjects with painful CP [12]. Not only was the intervention deemed feasible and acceptable, but the proportion of those who responded with reduced pain intensity and pain interference at 3 months was significantly greater in the internet-based CBT group than the control group. Psychological therapies show significant promise in CP patients with pain who are suffering from concomitant psychiatric illness and should be strongly considered in this patient subpopulation.

Although published literature on these types of interventions remains rare, patients who are suffering from painful CP and additional psychiatric illness may strongly benefit from referral to expert providers of psychosocial therapies, and there is at least some evidence that they are effective.

Treatments for Neuropathy

Neuropathy is an additional contributor to the experience of many patients with CP, and pain related to this can be particularly challenging to treat [5]. Alterations in pain processing due to changes in the nerves themselves or in patterns of transmission of pain signals can result in pain that is resistant to traditional analgesia.

Medications

Pregabalin, a lipophilic analog to the inhibitory neurotransmitter gamma-aminobutyric acid (GABA), has been approved by the US Food and Drug Administration for treatment of neuropathic pain and may have a role in treatment of painful CP. Pregabalin has previously been shown to reduce the pain intensity of patients with CP in a randomized, double-blind, placebo-controlled trial of 64 patients after 3 weeks compared to placebo [13]. In a separate placebo-controlled randomized trial of 90 patients, those who received a combination of antioxidant therapy and pregabalin were shown to have significant reduction in pain intensity, non-opioid analgesic requirement, and hospital admissions for pain during the 12-week study period compared to those who received placebo [14]. A randomized, double-blind, placebo-controlled study of 88 patients with recurrent pain following pancreatic ductal clearance additionally showed significant reduction of pain intensity after 8 weeks of therapy in those who received antioxidants and pregabalin compared with placebo [15]. It is noted that in the study from Sureshkumar et al. [13], patients with concomitant major depression, and those with intractable pain who had previously failed medical management were excluded, and in the study from Talukdar et al. [14], patients who had received high-potency narcotics were excluded. Given the prevalence of major depression and narcotic use among CP patients, these results are potentially difficult to extrapolate to the broader CP population. Additional neuromodulators including olanzapine, quetiapine, ketamine, and others may have effect in CP

pain though they have not been specifically studied in this population. The role of neuropathic agents is additionally discussed in the chapter on pain management, and the role of antioxidant therapy is further discussed in a dedicated chapter in this text.

Nerve Blocks

Blockade of specific nerves or nerve groups has been attempted for painful CP with varying degrees of success. Celiac plexus blockade is a technique performed via radiographic, CT-guided, or endoscopic-guided approaches in which steroids and local anesthetic are injected at the celiac plexus [16]. Response rates following therapy vary across studies but in general are lower than 60% [17,18]. The duration of response is only approximately 3–6 months, making this more of a temporizing measure than a treatment from which durable pain response is expected. Importantly, the risk of nerve damage associated with the procedure may actually worsen neuropathy, leading some to consider this treatment obsolete in painful pancreatic disease that is nonmalignant [19].

A small study of subcostal transversus abdominis plane blockade has shown reduction in pain from myofascial pain syndrome associated with CP [20]. This study was limited by the fact that the technique is ineffective for visceral pain as well as for pain from ongoing pancreatic inflammation: there was additionally no control arm making the results less robust. A single-blinded randomized crossover trial of acupuncture did show pain relief from treatment as compared to sham, but the effect was short-lived and disappeared after one week [21]. Several other small studies have shown some degree of benefit in research settings from experimental interventions including cervical transcutaneous neuromodulation, and transcranial magnetic stimulation [22,23]. The potential for clinical use of these techniques are limited by the fact that they are often administered only in research settings, require specific expertise, have short-lived effects, and are not widely available.

Central Sensitization

Central sensitization, a phenomenon of altered processing of nociception, has been described in patients with painful CP and is thought to be a critical aspect of the pain experience in this disease [24]. The presence of central sensitization has the potential to render traditional therapies such as decompression of an obstructed pancreatic duct or surgical drainage procedures ineffective in providing pain relief [25]. Techniques to reliably identify patterns of central sensitization including manifestations of widespread hyperalgesia or altered central pain modulation have previously been only available in research settings; however, a bedside technique intended for clinical adaptation has been recently developed [26]. Pancreatic quantitative sensory testing (P-QST) differentiates CP patients into distinct phenotypes by characterizing their nociceptive patterns and identifies patients with characteristics of central sensitization [27]. There is no treatment for central sensitization; however, both pregabalin and S-ketamine have shown promise in initial trials in modulating measures of hyperalgesia [28–30]. A randomized trial of S-ketamine treatment has been proposed but not yet completed [31].

Therapy for Nutritional Disorders

Malnutrition is a frequent complication of CP due to exocrine pancreatic insufficiency (EPI) and maldigestion [32]. This can be further exacerbated by concomitant disorders of delayed gastric transit, small intestinal bacterial overgrowth (SIBO), and sarcopenia [33–36]. While nutritional evaluation of CP is covered elsewhere in this text in detail, diagnosis of concomitant gastrointestinal disorders, vitamin and mineral deficiencies, and their treatment or supplementation may be effective adjuncts in the treatment of CP. Delayed intestinal transit, bloating from fat malabsorption, and neuropathy due to underlying vitamin deficiency are all possible sources of pain in CP complicated by malnutrition [37]. Diagnostic testing to include anthropometric, biochemical, and clinical markers of malnutrition for those patients at high risk on an annual basis have been recommended as a means of identifying those patients with possible vitamin and mineral deficiencies complicating their underlying CP [37].

Pancreatic Enzyme Replacement Therapy

Pancreatic enzyme replacement therapy (PERT) is designed to assist with the absorption of fat, protein, and micronutrients in EPI. Pain reduction from PERT is mostly secondary to decreased symptoms of maldigestion including hypermotility of the colon in the setting of steatorrhea, though some contribution from suppression of pancreatic enzyme release may be possible [38,39]. In a large systematic review and meta-analysis of clinical trials PERT has been shown to improve fat absorption in patients with CP both compared to patient baseline levels and compared to therapy with placebo [40]. In the same study, PERT was also shown to improve abdominal pain without significant adverse events. The perceived efficacy of PERT (by patients) for treatment of pain in CP in the absence of EPI was found to be low (36.3%); perceived efficacy of PERT rose only to 50% in patients with

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. both EPI and pain [41]. High-quality large rigorous studies on the efficacy of PERT for malnutrition in CP are needed, as is more consistent education for practitioners regarding indications for PERT therapy and potential benefit. Evaluation of an insured US population showed that both testing for EPI and adequate dosing of prescribed PERT were infrequent and inconsistent, suggesting that this therapy is underutilized and used in a suboptimal fashion in CP patients overall [42].

Vitamins, Antioxidants, and Octreotide

Fat-soluble vitamin levels are a frequent concern in patients with CP, especially in patients with symptoms of fat malabsorption. Vitamin D deficiency is the most common fat-soluble vitamin deficiency in CP patients (>50%), though it also common in patients without CP [32]. Vitamin A and E deficiencies have been seen in approximately 15% and 25% of CP patients, respectively [32]. Supplementation of fat-soluble vitamins is recommended to avoid the potentially serious complications of prolonged or severe deficiency including night blindness (vitamin A), neuropathy (vitamin E), and mineral bone disease such as osteopenia or osteoporosis (vitamin D). In particular, the prevalence of osteopathy in CP patients has been found to be significantly higher than that of the general population, and assessment and treatment has been recommended as part of routine care [43–45]. Diagnosis and supplementation of water-soluble vitamin and micronutrient deficiencies in patients with poor diet or other markers of malnutrition are also recommended.

Indications for, efficacy of, and evidence regarding antioxidant use is reviewed in a separate chapter, but they are mentioned here as part of the adjunctive armamentarium for painful CP, through reduction of acinar cell injury by protecting against oxidative stress [41]. It is noted that their use is infrequent and dosing is quite varied across practitioners, and reported data has been highly variable on their efficacy [41,46,47]. Similarly, octroeotide—a synthetic somatostatin analog that has an inhibitory effect on pancreatic secretion—has been utilized to decrease pancreatic stimulation and release of enzymes. Its use in CP has been infrequent, and the reported efficacy for symptoms of CP has been highly variable [41].

Cannabinoids

Reported cannabinoid use has increased in recent years as an analgesic agent for patients with painful CP concomitant with the spread of medically directed marijuana therapies, though high-quality randomized study data is scarce and cannabinoids represent a heterogenous group of chemical substances [48]. Delta-9 tetrahydrocannabinol (THC), the most abundant cannabinoid in the plant, was tested in a phase-2 placebo-controlled clinical trial of patients with chronic abdominal pain, but unfortunately did not show any significant improvement compared to placebo [49]. This study was notably limited by heterogeneity of the etiology of abdominal pain in the studied patients, with CP and post-surgical patients combined into a single group. A separate small study was not designed to evaluate pain response to cannabis, but detected a reduction in opioid use, hospitalizations, and emergency room visits for CP patients after their enrollment in a state-directed therapeutic cannabis program compared to before their enrollment in the program [50]. A recent observational study shows that medical marijuana is used more frequently in patients maintained on chronic opioid therapy than those who are not on chronic opioids, suggesting that its utility is mainly seen as an adjunctive agent in this patient population [51].

Conclusions

Adjunctive therapies in CP are initiated because existing analgesic and interventional therapies result in suboptimal relief of symptoms for this disease. A thorough evaluation for concomitant and complicating disorders should be conducted, and directed adjunctive agents can be initiated based on the individual patient situation after traditional therapies for CP have been optimized. The evidence for the efficacy of adjunctive therapies in CP remains quite limited even though there are hints that they can form part of an overall treatment regime for painful CP.

Introduction

In the late nineteenth century, the German pathologist Rudolf Virchow proposed that there was a close link between inflammation and cancer, based on cellular studies made possible by microscopy. Since then it has been observed that inflammatory diseases such as esophagitis, gastritis, and colitis sometimes precede the development of cancer in these organs. Throughout the twentieth century, anecdotal reports of pancreatitis preceding pancreatic cancer have emerged. These isolated reports suggested a possible link between chronic pancreatitis and pancreatic cancer and eventually led to a large retrospective cohort analysis conducted near the end of the twentieth century. In this chapter, we review and summarize the evidence linking chronic pancreatitis and pancreatic cancer.

Descriptive Findings

Acute pancreatitis, chronic pancreatitis, and pancreatic cancer are the three most common pancreatic diseases. How does their incidence compare? Acute pancreatitis is one of the commonest gastrointestinal disorders and has an estimated incidence of about 13–45/100,000 per year [1]. The incidences of chronic pancreatitis and pancreatic cancer are similar to each other, with age-standardized incidence rates of around 10/100,000 per year.

Figure 61.1 illustrates the relationship between these three diseases and the potential pathways for progression from acute to chronic pancreatitis and, in some patients, to pancreatic cancer. In patients with gallstone-related pancreatitis, cholecystectomy performed on a timely basis eliminates the major source for gallstones and precludes additional attacks. However, acute pancreatitis also develops from many other causes, and if the cause is heavy drinking, smoking, autoimmunity, or a

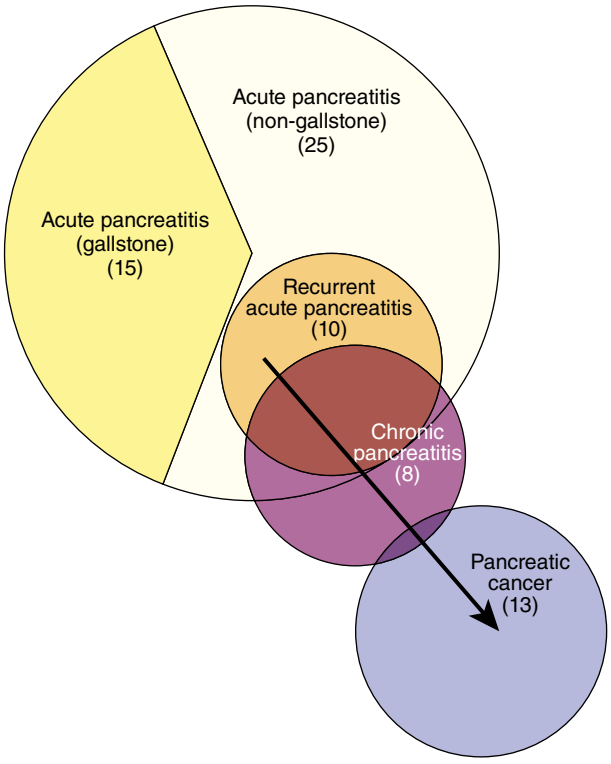

Figure 61.1 Incidence rates for pancreatic diseases in the United States. Numbers inside circles indicate incidence rates per 100,000 population. The arrow indicates the progression from benign to malignant disease. Note the small overlap between the circles representing chronic pancreatitis and pancreatic cancer. *Source:* Yadav and Lowenfels 2013 [1]. With permission of Elsevier.

genetic disorder, recurrent attacks of acute pancreatitis (recurrent pancreatitis) may occur and disease progression may then lead to chronic pancreatitis. Of patients who develop chronic pancreatitis, a small proportion will develop pancreatic cancer. The average age at diagnosis of chronic pancreatitis in patients with alcohol-related disease is about 45–55 years, approximately a decade earlier than the average age of onset of pancreatic cancer. This time sequence indicates that the direction of causality is compatible with a progression from benign to malignant disease.

Other than age, what are some of the other similarities and differences between chronic pancreatitis and pancreatic cancer? For both diseases, smoking and obesity are recognized risk factors, whereas heavy drinking, which is strongly linked to chronic pancreatitis, is associated only with a modest increased risk for pancreatic cancer [2]. Both diseases are also more frequent in black than in white populations, and diabetes frequently accompanies both diseases.

Measuring the Strength of the Pancreatitis–Pancreatic Cancer Association

After initial reports from single centers by Ammann and coworkers in 1984 [3] and Rocca and coworkers in 1987 [4] who described the gradual increase of pancreatic calcifications and pancreatic dysfunction with increasing duration of the disease and suggested an increased risk of pancreatic, as well as extrapancreatic cancer, in patients with chronic pancreatitis, Lowenfels and coworkers conducted the first multicenter cohort study. Among 2015 patients with well-documented chronic pancreatitis from six countries followed up for a minimum of 5 years after the diagnosis of chronic pancreatitis, the risk of pancreatic cancer was 14.4 (95% Cl: 8.5–22.8) times higher than that in the background population. The risk was similar in all study countries and in patients with either alcoholic or nonalcohol pancreatitis [5]. Over a follow-up period of up to 20 years, the cumulative incidence of pancreatic cancer was 4%. This implies that chronic pancreatitis, although a strong risk factor, explains only a small proportion of the total burden of pancreatic cancer. Also in contrast to the 29 patients who died from pancreatic cancer, 137 patients in the group died from other types of cancers. Because of lifestyle factors such as smoking and heavy alcohol drinking, most cancer deaths in patients with chronic pancreatitis will be from nonpancreatic cancer.

Since publication of this report, several additional studies have looked at the relationship between chronic pancreatitis and pancreatic cancer [6–29]. Raimondi and coworkers published an initial meta-analysis in 2010 based on 18 additional studies [30] with a pooled relative risk (RR) of 13.3 (95% CI: 6.1–29) for well-defined chronic pancreatitis. In 2014, Tong and coworkers published a systematic review of epidemiologic studies linking pancreatitis and pancreatic cancer [31]. This report contained 14 case-control studies and 3 cohort studies and found a pooled odds ratio of 7.1 (95% CI: 6.4–7.8). As in the previous meta-analysis, the results were stronger in cohort studies than in case-control studies. In a large pooled analysis of 10 case-control studies, Duell and coworkers reported a nearly threefold increased risk of pancreatic cancer in patients where there was a minimum of 2 years separating the diagnosis of pancreatitis from pancreatic cancer [10] More recent reviews and meta-analyses were performed by Kirkegard and coworkers [32] and Ghandi and coworkers [33]. Based on these reports and more recent studies, we prepared an updated meta-analysis of 26 studies, stratified by broad type of chronic pancreatitis (Fig. 61.2). The pooled risk estimates are as follows: RR = 12.0 (95% CI: 7.7–18.7) for 19 studies in patients with definite chronic pancreatitis [3,5–22], RR = 69 (95% CI: 56–85) for three studies in patients with hereditary pancreatitis [23–25], RR = 109 (95% CI: 56–211) for two studies in patients with tropical pancreatitis or similar forms of idiopathic pancreatitis from India [26–27]. For two studies comparing the risk of pancreatic cancer in *SPINK1*-related pancreatitis compared to idiopathic pancreatitis, the pooled RR = 20.3 (95% CI: 9.1–45.3) [28–29].

Among recent major representative studies, a nationwide report from Denmark provides further evidence for a strong link between pancreatitis and pancreatic cancer [16]. In this follow-up study of nearly 12,000 patients with chronic pancreatitis and nearly 120,000 matched controls the authors found a 6.9-fold increased risk of death from pancreatic cancer in pancreatitis patients compared with the control population. Again, the risk of pancreatic cancer was similar in patients with either alcoholic or nonalcoholic pancreatitis. Based on an electronic medical record system, Hao and coworkers [18] examined data from 1656 patients with chronic pancreatitis from Shanghai Hospital, China and confirmed a markedly increased risk of pancreatic cancer (SIR = 20.2; 95% CI: 12.5–30.9) especially in heavy smokers. More recently, Munigala and coworkers [21] performed a retrospective study of US Veterans Administration identifying as many as 21,785 patients with chronic pancreatitis, of whom 226 developed pancreatic cancer 2 years after chronic pancreatitis (HR = 4.28; 95% CI: 3.74–4.89). The risk was consistent and sustained beyond 5 years and 10 years of follow-up. Finally, Vujasinovic and coworkers assessed the cumulative incidence of pancreatic cancer in 581 patients with definite chronic pancreatitis from Karolinska University Hospital, Stockholm, Sweden [34]. Excluding patients diagnosed with pancreatic cancer

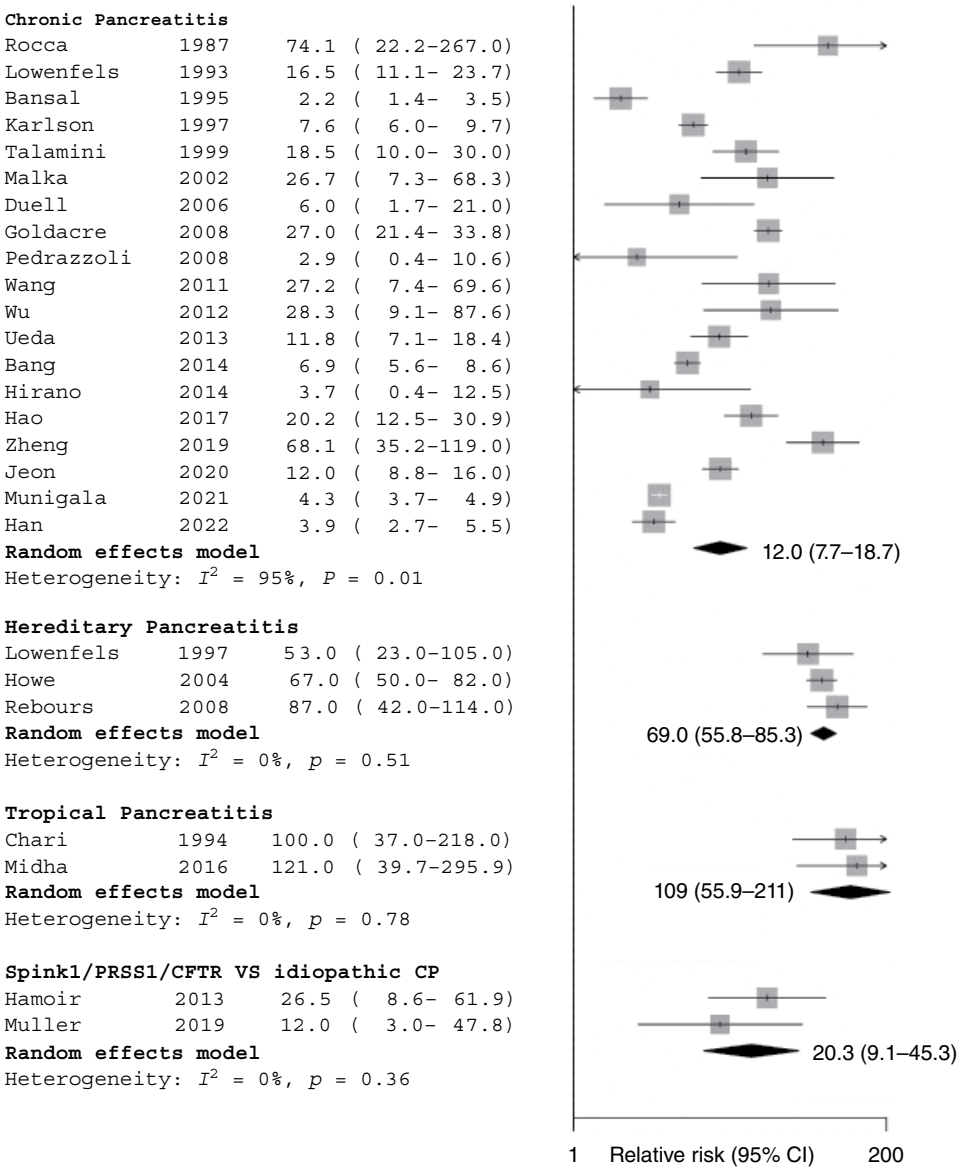

Figure 61.2 Meta-analysis showing study-specific and summary risk estimates with 95% confidence intervals for the association between different types of pancreatitis and pancreatic cancer.

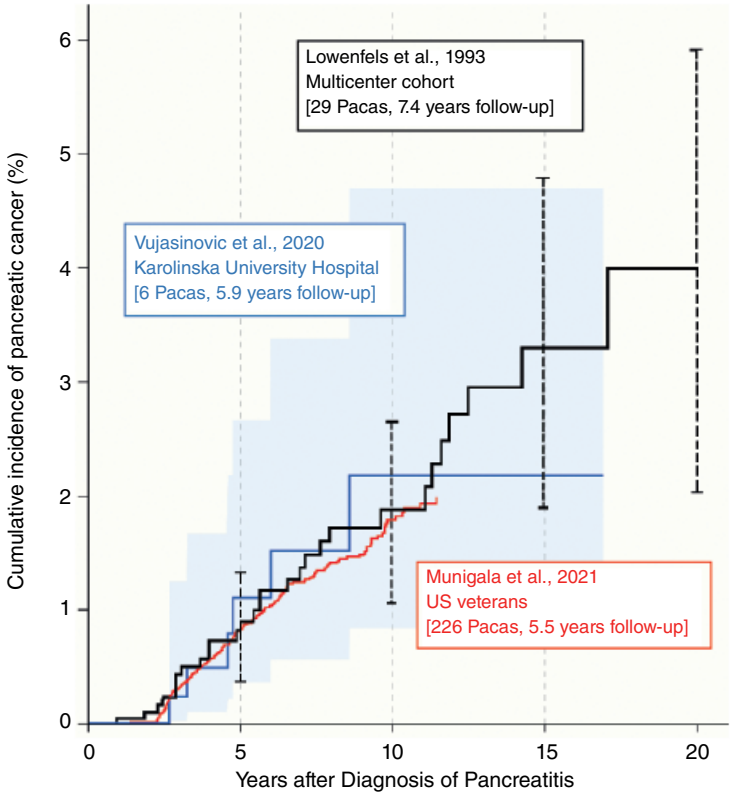

within 2 years from the diagnosis of chronic pancreatitis, the incidence rate of pancreatic cancer was 0.2% annually, a rate similar to that observed in the initial multicenter study by Lowenfels and coworkers [5] and the latest Veterans Administration study [21] (Fig. 61.3).

Discussion

Reviewing the evidence accumulated over several decades reveals a strong link between chronic pancreatitis and pancreatic cancer. Clinicians must still be aware of reverse causality because one symptom of pancreatic cancer can be sudden onset of pancreatitis in the absence of known risk factors. However, the evidence from several long-term follow-up studies with exclusion of early-onset pancreatic cancer confirms the pancreatitis–pancreatic cancer link. The findings of this relationship in the pancreas agrees with information from other organs, and confirms Virchow's nineteenth-century hypothesis. As yet we do not have a full understanding of the mechanisms underlying the transformation from a nonmalignant disease to cancer.

All the reports indicate that the cumulative risk of pancreatic cancer in patients with long-standing confirmed chronic pancreatitis is low—probably less than 5%. This implies that until we develop noninvasive screening procedures with greater sensitivity and specificity than are currently available, screening patients with chronic pancreatitis is not likely to be rewarding.

Figure 61.3 Cumulative incidence of pancreatic cancer in patients with chronic pancreatitis from three selected cohort studies [5,21,34].

Hereditary pancreatitis due to inherited *PRSS1* mutations is a rare inherited autosomal dominant genetic disorder that causes early-onset pancreatitis characterized by recurrent attacks eventually leading to chronic pancreatitis. As with other risk factors, such as smoking, long duration of exposure increases the risk of cancer. Because patients with this type of pancreatitis have about a 70% lifetime risk of developing pancreatic cancer, already in 2001, minimally invasive imaging screening with endoscopic ultrasound (EUS), multiphasic helical computed tomography (CT) or magnetic resonance imaging/magnetic resonance cholangiopancreatography (MRI/MRCP) have been proposed for patients with the hereditary pancreatitis phenotype, beginning at the age of 40 years [35]. Recent international consensus guidelines recommend surveillance in affected individuals with hereditary pancreatitis due to inherited *PRSS1* mutations, but estimate that the risk of pancreatic cancer in patients with chronic pancreatitis associated with *SPINK1* or other germline mutations including those of *CFTR*, *CTRC*, *CPA1*, and *CEL* is not high enough to justify surveillance [36].

What are fruitful areas for additional research that might benefit patients with underlying pancreatitis? Pancreatic cysts are now being detected with increasing frequency and we need to be able to identify or confirm subgroups of these patients who have an increased risk of pancreatic cancer [37].

Pancreatic cancer can mimic nonmalignant disease such as autoimmune pancreatitis, leading in some patients to unnecessary pancreatic surgery [38,39]. We need to develop biological tests and/or biomarkers that can reliably distinguish between chronic pancreatitis and pancreatic cancer. Finally, collecting and storing biologic samples from patients with well-documented chronic pancreatitis will help us improve our understanding of the gradual transition of pancreatitis to pancreatic cancer.

The irreversible pathologic changes characteristic of chronic pancreatitis make this disease difficult to treat and the progressive cellular disruption of glandular and ductal tissues leads eventually, in some patients, to pancreatic cancer. Efforts to reduce lifestyle factors such as smoking and alcohol drinking in patients with recurrent

bouts of acute pancreatitis offer an opportunity to reduce the burden of this disabling disease and prevent the occurrence of pancreatic cancer [2]. Advising all patients with CP to lead a healthy lifestyle aimed at avoiding risk factors for progression of CP and pancreatic cancer was specifically emphasized in the recent international consensus guidelines on surveillance for pancreatic cancer in chronic pancreatitis [36].

Evidence of Endoscopic and Interventional Treatment of Chronic Pancreatitis and Pseudocysts

Jörg Schirra[1], *Simon Sirtl MD*[1], *Markus M. Lerch*[2], *and Julia Mayerle*[1]

[1] *Department of Medicine II, LMU University Hospital, Ludwig-Maximilians-University, Munich, Germany*
[2] *LMU University Hospital, Munich, Germany*

Indications for Interventional Endoscopic or Surgical Therapy

Belt-like upper abdominal pain is regarded as a cardinal symptom of chronic pancreatitis (CP), together with weight loss, steatorrhea, and diabetes mellitus. In the absence of causal therapeutic options, treatment is restricted to symptom control by means of enzyme replacement, pain therapy, and optimal control of endocrine insufficiency. The complexity of disease management is justified as morphology on imaging and pain level do not correlate in most patients and an impressive ductal obstruction or intraductal calcification may be associated with little pain and subtle findings on imaging may be associated with a significant loss of quality of life due to constant pain [1]. Comparative trials with sham interventions to evaluate the placebo effect or the natural course of the disease have rarely been conducted, one example being the trial by Seza et al. Between 30% and 60% of patients develop complications of their disease such as strictures of the common bile duct, inflammatory masses, pancreatic pseudocysts, or pancreatic duct strictures or ductal stones, which require interventional or surgical treatment. Chronic pancreatitis with severe pain requiring constant analgesics should be treated by interventional or surgical procedures dependent on the symptom-causing pathogenic features [2]. The presence of an inflammatory mass clearly favors a surgical resection. In the case of a dilated pancreatic duct due to strictures and/or ductal stone both endoscopic as well as surgical drainage procedures are effective. The indication of an endoscopic drainage has not been fully clarified in randomized controlled trials (RCT). Endoscopic treatment of a dominant stricture of the main pancreatic duct is often followed by pain relief in the short term [3,4]. Retrospective studies have reported long-term pain relief in 32–68% of patients [4]. Two randomized controlled studies directly compared endoscopic procedures with resection or a surgical drainage procedure [1,5,6]. Those studies proved surgery to be superior to endoscopy with respect to long-term outcome; however, due to limitations in the study design, a reliable evidence-based assessment remains difficult under the current lack of consideration of the placebo effect, the natural course, and a possible selection bias. Nevertheless, endoscopic drainage can achieve a long-lasting complete or partial pain relief in at least one-third of patients; it is associated with lower mortality and does not impede surgery as a second-line therapy [6]. In the presence of a resectable pancreatic mass suspected to be caused by pancreatic carcinoma surgical resection should be performed. Without surgery, life expectancy for patients with pancreatic carcinoma is less than 1 year; after successful resection 20–25% of patients may survive more than 5 years [7–9]. Gastric outlet obstruction secondary to CP requires surgical or endoscopic treatment for persistent clinical symptoms. A noninterventional management supplemented by endoscopic dilatation may be sufficient for an adequate quality of life in at least 30% of cases. According to the natural course of CP further intervention will be necessary in about 30–60% of patients [10]. As there are no studies directly comparing the efficacy of pancreatic head resection, bypass surgery, and endoscopic insertion of self-expanding metal stents (fcSEMS) [11], the decision may be taken in view of the patient's comorbidities. Symptomatic stenosis of the common bile duct (CBD) will develop in 10–40% of cases requiring endoscopy with dilation and stent insertion. The outcome of endoscopic therapy in patients without acute inflammation of the pancreas has improved with

new techniques but is still not entirely satisfactory. Stent therapy rarely resolves a stricture beyond 1 year of therapy [12], in particular in the presence of calcifications within the pancreatic head [13]. Lasting patency rates have significantly improved with the use of fcSEMS. Surgical resection should be performed if symptoms or cholestasis persist after temporary endoscopic therapy not longer than a year. For obstructive chronic painful pancreatitis with ductal dilatation of more than 5 mm, a recent trial (ESCAPE) recommended earlier surgery after a maximum of 6 months of opiate pain medication without clinical improvement or preceded by 3 months of endoscopic therapy without symptom improvement [14]. Fragmentation and removal of stones within the pancreatic duct by extracorporeal shock wave lithotripsy (ESWL) have somewhat replaced surgery since its introduction in 1989. Several retrospective studies have shown ESWL as an effective and safe management option for pain relief in chronic calcifying pancreatitis with pancreatic main duct stones greater than 5 mm [15], for which ESWL followed by ERCP may be the standard of care. Intraductal lithotripsy under direct endoscopic vision is a promising technique in evolution. Interventional endoscopic options in CP will be discussed in more detail below.

Treatment of Pancreatic Cysts

According to the revised Atlanta classification a pancreatic pseudocyst is an encapsulated collection of fluid with a well-defined inflammatory wall usually outside the pancreas with minimal or no necrotic tissue content. This entity usually arises in connection with CP [16]. A walled-off necrosis (WON) is defined as a mature, encapsulated collection of pancreatic and/or peripancreatic necrosis that has developed a well-defined inflammatory wall. WON usually occurs >4 weeks after the onset of necrotizing pancreatitis [16]. The prevalence of pancreatic pseudocysts in CP ranges between 20% and 40% [17]. They occur with the highest frequency in patients with alcoholic CP (70–78%), followed by idiopathic CP patients (6–16%), and biliary pancreatitis patients (6–8%) [17,18]. Approximately 40% of the fluid collections resolve spontaneously within the first 6 weeks after an acute attack of pancreatitis. In contrast, spontaneous remission of pseudocysts after 12 weeks is a rare event. Complications are observed in up to two-thirds of cases encompassing pain, infection, hemorrhage, cystic rupture, or obstruction of adjacent organs such as cholestasis, gastric outlet obstruction, or vascular stenosis. A multivariate analysis showed a pseudocyst/WON size <4 cm as the only favorable factor for spontaneous resolution [19]. The increase in size of a pseudocyst/WON to over 5 cm in diameter is associated with an increased risk of complications [20]. Asymptomatic pseudocysts >5 cm in diameter which do not resolve within 6 weeks can be an indication for treatment. The aim of this intervention is to avoid possible complications that may occur later in the course of the disease, such as a cyst rupture, infection or hemorrhage, the likelihood of such complications being approximately 50%. However, symptomatic pseudocysts should undergo treatment regardless of their size.

Only limited information is available with regard to interventional therapy of pancreatic pseudocysts for pain management. Most of the data at hand are based on retrospective case series [21–24], but three systematic reviews are available [25–27]. Pain relief will be achieved in a large number of patients (about 80%). Although medical management of CP can result in pain relief, in a certain percentage of patients, interventional or surgical drainage is still the more effective form of pain management regardless of the drainage procedure.

A diagnostic needle aspiration of the cyst may be performed for suspected infection or for suspected cancer. If needle aspiration of the cyst confirms an infection, then drainage is indicated. Surgical treatment should be carried out if malignancy is suspected. In 28% of all MRI scans of the abdomen, a cystic lesion of the pancreas is discovered as an incidental finding [28] when population-based cohorts are investigated, albeit most of these cysts are smaller than 1 cm in diameter. More than two-thirds of these lesions are dysontogenetic cysts or pancreatic pseudocysts. Of the cystic lesions that are not pancreatic pseudocysts but genuine cystic neoplasms, 30% are benign serous cystadenomas. Forty-five percent of the resected lesions are mucinous-cystic neoplasms and 25% intraductal papillary mucinous neoplasms (IPMN). Solid pseudopapillary tumors or cystic acinar cell carcinoma are rather rare entities. For the differential diagnosis of cystic tumors in asymptomatic patients, the question of a connection to the pancreatic duct (IPMN and pancreatic pseudocysts) and of the size of the cystic lesion (indication for resection in the case of IPMN or therapeutic indication for pseudocyst) is essential. Diagnostic needle aspiration of a cyst with the aid of EUS helps in differentiating between premalignant cystic neoplasms, cystic malignancies, and pseudocysts. In case the fluid analysis reveals a CEA >400 ng/mL, a variably increased or low amylase (lipase), high viscosity, mucin or epithelial cells in the cyst content, then a mucinous neoplasm must be assumed [28–30]. In addition to CEA and amylase/lipase, low pancreatic cyst fluid glucose has been established as a marker for the differentiation of mucinous versus non-mucinous pancreatic lesions. In 609 cystic lesions examined, a systematic review showed significantly increased pooled sensitivity (91% vs. 56%; $P < 0.001$)

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. and diagnostic accuracy (94 % vs. 85 %; $P < 0.001$) compared to CEA alone [31].

If a connection to the pancreatic duct is excluded the final diagnosis of a mucinous cystic neoplasm (MCN) can be made. A serous cystadenoma is diagnosed in 30% of cystic lesions and virtually never turns into a malignant lesion. In this case aspiration of the cyst is negative for mucin, CEA, and amylase. Cytology reveals a glycogen-rich epithelium. Surgical, percutaneous, or endoscopic drainage of pancreatic pseudocysts demonstrate comparable results regarding technical success, efficacy, and recurrence rates [26,32]. Percutaneous drainage is associated with the risk of external fistula and may affect the patient's quality of life. Endoscopic drainage is less prone to complications when compared to surgical procedures. A systematic review of retrospective series of endoscopic and surgical drainage showed similar morbidity (13.3% vs. 16%) and long-term pseudocyst recurrence (10.7% vs. 9.8%) but lower mortality (0.2% vs. 2.5%) achieved by an endoscopic drainage [33]. Therefore, the endoscopic approach should have first preference as it is less invasive and more convenient for the patient. In a recent RCT that compared endoscopic versus surgical cystogastrostomy for pancreatic pseudocyst drainage endoscopic treatment was associated with shorter hospital stays, improved physical and mental health status of the patients, and lower costs [32]. However, the decision between endoscopic and surgical drainage should take into account the cyst location and additional pathophysiological features. Surgical drainage may be the preferable therapy in hemorrhagic pseudocysts as endoscopic drainage is associated with a higher risk of bleeding. Approximately 10% of pseudocysts recur in the long term after endoscopic drainage (Table 62.1). Although initial therapy of nonhemorrhagic pseudocysts should be endoscopic drainage, surgery may follow in case of recurrence. Drainage of pseudocysts can be carried out by transgastric, transduodenal, or transpapillary routes. Transmural drainage should be done under endoscopic ultrasound (EUS) guidance to assess the pseudocyst location, size, wall, content, and adjacent blood vessels. Two RCT compared transmural drainage with and without EUS guidance [34,35]. No difference was observed in terms of morbidity and clinical outcome but technical success was higher with EUS. The success rate in 1018 published patients with transmural drainage of a pseudocyst was 87% (Table 62.1), with more recent studies reporting success rates of more than 90%. The mortality rate in larger case series involving more than 30 patients was 0.2%, the recurrence and complications rates are reported to be around 9% and 13%, respectively. Without antibiotic prophylaxis the procedure-related incidence of an infection of a pseudocyst and the risk of development of a pancreatic abscess increases [36,37]. Antibiotic prophylaxis for transmural or transpapillary drainage of pancreatic pseudocysts is recommended in recent guidelines based on expert opinion [4,38]. Double-pigtail stents should be used for transmural drainage of pancreatic pseudocysts because straight stents are associated with more frequent and severe complications in a retrospective study [39]. Early stent retrieval within 2 weeks after cyst resolution was associated with a higher rate of recurrence in a prospective randomized trial suggesting that long-term stent placement for more than 2 months may prevent recurrence without an increase of severe adverse events [40]. In its clinical guideline ESGE recommends transmural drainage of pancreatic pseudocysts by inserting at least two double-pigtail plastic stents, which should not be retrieved before at least 2 months of stenting [4]. Recently, short, lumen-apposing, fully covered, self-expandable metal stents (LAMS) have been developed for EUS-guided drainage of peripancreatic fluid collections.

In CP with advanced pancreatic ductal changes, especially with pancreaticolithiasis, a pseudocyst should be considered and treated as part of an overall therapeutic concept. For small pancreatic cysts, the tendency to regress due to persistent inflammatory stimuli is a maximum of 26%, so that even in the case of small symptomatic cysts, an interventional or surgical procedure may be considered in the individual patient context.

Due to its ease of use and the large diameter, the LAMS may make drainage of peripancreatic fluid collections more effective, particularly the endoscopic debridement of WON [41,42]. Despite initial reports on bleeding, recent meta-analyses demonstrated superior efficacy and safety compared to plastic stents in the management of peripancreatic fluid collections [43,44]. The basic question of an ideal timing for WON drainage in case of infected pancreatic necrosis has been studied in the POINTER trial. With regard to mortality and the comprehensive complication index (which includes all major complications), there was no significant difference between immediate catheter drainage (catheter drainage within 24 hours after randomization) and postponed catheter drainage (stage of walled-off necrosis, when necrotic collections were largely or fully encapsulated). However, the cohort of the later WON drainage installation (partly percutaneous, partly EUS-assisted) required fewer interventions overall, especially in terms of the number of necrosectomies required, and patients stayed in hospital for a correspondingly shorter time [45]. Of note, the median time to "immediate catheter drainage" was after a mean of 24 days (median, 24 days; interquartile range, 20 to 30) after onset of symptoms and postponed catheter drainage after a mean of 34 days (median, 29 days; interquartile range, 24 to 40) after onset of symptoms (mean difference, –10 days; 95% confidence interval [CI],

–19 to –5) and thus even "the immediate drainage group" followed current guideline recommendations.

Whether an ERCP with the attempt of draining the pseudocyst via the papilla should be performed instead of a primarily transgastric or transduodenal drainage is still a matter of controversy. According to retrospective studies, transpapillary drainage seems to be associated with lower morbidity (mainly pancreatitis) and similar long-term success but was used for smaller pancreatic cysts than transmural drainage [4,46–48]. It is reported that 22–57% of pancreatic pseudocysts may have a connection with the pancreatic ductal system [49]. Thus, an ERP can precede endoscopic transmural drainage in order to detect a connection with the duct or to exclude a rupture of pancreatic ducts (8% after acute necrotizing pancreatitis). Transmural drainage in the presence of an undetected rupture of the pancreatic duct or an association of the pancreatic pseudocyst with an obstructed pancreatic duct is less promising with regard to long-term outcome of therapy [50,51]. Treatment of pancreatic duct obstruction and—if possible—bridging of a pancreatic duct rupture is recommended in these cases.

Therapy of Pancreatic Duct Stenoses and Ductal Stones

Ductal and interstitial hypertension and possible pancreatic ischemia accompanying outflow obstruction due to pancreatic duct stenoses or ductal stones may play an

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. important role in the pathogenesis of pain. The aim of endoscopic and surgical decompression therapy in patients with CP and pain and/or clinical episodes of acute pancreatitis is to remove the obstruction and to allow outflow of exocrine pancreatic juices into the duodenum. Biliary techniques such as sphincterotomy, dilatation, ESWL, and stent insertion have been modified for the pancreatic duct. Endoscopic decompression represents an alternative to surgery and is associated with low morbidity and low mortality. Endoscopic interventions do not interfere with surgery that might still be necessary later in the course of the disease. Clinical success after endoscopic reduction of the intraductal pressure does provide some indication of the later result of surgical drainage or a resection procedure.

Pancreatic ductal stones are a consequence rather than the cause of CP. They can, however, lead to consecutive outflow obstruction and thus cause pseudocysts or fistulae development, recurrent exacerbations or contribution to the pathogenesis of pain. Under these conditions, treatment of pancreatic ductal stones seems appropriate. Endoscopic treatment appears particularly suitable for treating solitary stones and obstructions close to the papilla or in the body of the pancreas. After pancreatic sphincterotomy, pancreatic duct stones <5 mm may be extracted without prior fragmentation. Radiopaque obstructing stones ≥5 mm should be fragmented by ESWL followed by extraction of the fragments by ERCP [4]. There is evidence from a prospective randomized trial that the subsequent endoscopic removal of the fragments is not a prerequisite for the effectiveness of the procedure [52]. One large-scale single-center retrospective study with follow-up of 272 patients after ESWL and ERCP for >60 months reported no pain in 60% of patients, mild to moderate pain in 36%, and episodic severe pain in 4% of patients [53]. Recurrence of intraductal calculi was seen in 23% of patients. A recent meta-analysis of 27 studies (total of 3189 patients) showed that ESWL is useful for clearing pancreatic duct stones greater than 5 mm and for decreasing pain [15]. The pooled proportion of patients with absence of pain at follow-up (median 2 years) was 53% (95% CI: 50.8–54.6) and mild to moderate pain was 33% (95% CI: 31.4–35.5). Quality of life improved in 88% and complete ductal clearance was achieved in 71%. However, no studies have compared the treatment of ductal stones with the natural course or a sham intervention. In principle, individual pancreatic duct stones that cause pain due to obstruction of the outflow of pancreatic secretion are treated with ESWL, pancreaticoscopic electrohydraulic lithotripsy or laser lithotripsy. A current prospective study investigating the effectiveness of direct EHL-guided lithotripsy showed promising results regarding feasibility and safety of EHL [54].In two older studies, in which endoscopic treatment was compared with surgery, i.e., drainage operation, the results after surgery were significantly better with respect to long-term pain reduction [1,5]. Recent data from the multicenter, prospective ESCAPE trial point in the same direction. Patients with symptomatic pancreatic duct stenosis, a blockage of the pancreatic duct and a duct width of >5 mm experienced an advantage of early surgery compared to a "step-up approach" with optimized medical therapy, endoscopic intervention, and “delayed” surgery: complete or partial pain reduction at 18-months follow-up in 58% vs. 39%; $P = 0.1$) [14]. However, neither the complication rate of surgery nor surgical mortality were taken into account as endpoints, which are nevertheless of considerable importance in guiding patients. The treatment of pain in patients with diffuse calcifications by means of ESWL has not been substantiated in any studies.

Patients with dominant pancreatic duct strictures with a prestenotic dilatation ≥6 mm in diameter, which may be responsible for pain, recurrent exacerbations, maintenance of a pseudocyst, fistula, or other complications, can be treated by endoscopic dilatation and plastic stent placement [4]. Removal of the obstruction of the pancreatic duct is effective for the treatment of pain on short to intermediate terms. Success rates between 65% and 95% have been reported [4]. In the largest hitherto examined cohort of 1021 patients, a long-term reduction (mean 4.5 years) of pancreas-related pain was achieved in 85% of cases [55]. However, 24% underwent surgery during further follow-up, which—on an intention to treat basis—reduced the rate of successful treatment to 65%. In 79% of the patients stent therapy for control of pain had to be repeated within 1 year and in 97% within 2 years. The only randomized study recruited 41 consecutive patients with CP with a dominant pancreatic duct stricture to either receive pancreatic duct stenting or to serve as control. During a mean follow-up of 62.5 ± 20.9 months pain recurred in 15% of patients with pancreatic duct stenting (3/20) and in 50% of control patients (11/22) ($P < 0.05$). Progression of exocrine insufficiency in the stent group was significantly slower than in the control group ($P < 0.05$), while endocrine function showed no difference between groups [56]. Preliminary studies suggest temporary placement of fcSEMS into the pancreatic duct for pain relief may be a safe and effective short-term treatment [57–59]. Their potential advantage versus plastic stents is the longer period of stent patency. A recent meta-analysis found fcSEMS comparable to multiple plastic stents in the treatment of symptomatic refractory pancreatic duct strictures, but the risk of adverse events was increased [60]. However, long-term results are so far not available. Uncoated self-expandable metallic stents are not recommended due to the rapid proliferation of duct epithelium as a reaction to the metal

mesh graft. Plastic stents inserted into the pancreatic duct can induce secondary changes with subsequent fibrosis and strictures [61,62]. There are currently no reliable data available regarding the necessary duration of stent therapy. Some authors recommend treatment over 1 year with an exchange of the stent at least every 3 months [4]. Other centers suggest exchanging the stent in case of reoccurring symptoms. A question which should be solved in a randomized trial. Improved pain management, however, was achieved by a pancreatojejunostomy in two RCT [1,5,6]. Endoscopic therapy led to pain reduction or complete pain relief in 32% [5] and 61% [1], respectively, whereas this was achieved in 75% [5] and 86% [1], respectively, by pancreatojejunostomy. However, endoscopic drainage can achieve a long-lasting complete or partial pain relief in a substantial proportion of patients, and does not impede surgery as a second-line therapy.

Endoscopic Treatment of Bile Duct Obstruction

Obstruction of the common bile duct (CBD) will develop in 3–46% of patients with CP [63]. Indications for endoscopic intervention include significant cholestasis, cholangitis, prevention of secondary biliary cirrhosis, and differentiation of the cause of pain (obstruction of the CBD vs. CP). Long-term success rates can be achieved in one- to two-thirds of the patients dependent on the endoscopic drainage modality [4]. Thus endoscopic therapy is indicated as an interim procedure until definitive surgery, for example as an acute intervention in septic patients, or in patients unfit for surgery, or in those unwilling to undergo surgery. Complications include stent occlusion and cholangitis. Prophylactic antibiotic therapy together with ursodeoxycholic acid has not been proven to be effective [64–66]. Endoscopic drainage should, therefore, be of limited duration.

Immediate endoscopic drainage should be performed in the case of obstructive cholangitis. Although no published studies have compared endoscopic therapy to observation without drainage as treatment of mechanical cholestasis as part of the therapy for cholangitis is important and well substantiated by clinical experience. If CP causes distal obstruction of the bile duct with cholestasis or obstructive jaundice, then either surgical treatment or endoscopic stent therapy can be performed. A retrospective analysis of all patients treated with an average observation period of 45 months demonstrated that stent therapy for the obstruction of the CBD in patients with CP has no additional effect beyond 1 year [12]. Surgical treatment should therefore be pursued for recurrence of CBD obstruction after 1 year of stent therapy. A prospective study showed an even worse long-term effect of stent management of distal bile duct obstruction in patients with calcifying pancreatitis (long-term effect 9%) [13]. In these cases surgical treatment is clearly preferred.

The placement of multiple plastic stents into the biliary stricture of patients with CP is superior to insertion of single plastic stents. In prospective, nonrandomized and retrospective studies the success rate after insertion of up to five plastic stents into the CBD was higher than after a single stent with long-term success rates of up to 92% of patients during a period of 12–48 months after stent removal [67–69]. A prospective nonrandomized study at 13 centers in 11 countries treated 187 patients with benign biliary strictures by fcSEMS [70]. Removal was scheduled at 10–12 months. On an intention-to-treat basis the stricture resolution rate was 76%, and the rate of stricture recurrence was 14.8% (95% CI: 8.2–20.9%) during follow-up of 20 months. Thus, effective long-term success was achieved in 62.7% of patients. A randomized controlled study compared insertion of multiple plastic stents with a single fcSEMS in 112 patients for treatment of benign biliary strictures during 1 year [71]. The resolution rate of biliary strictures was 85.4% with plastic stents and 92.6% with fcSEMS ($P < 0.001$). The mean number of ERCP to achieve resolution was significantly lower for fcSEMS than for plastic stents. The recurrence rate within 1 year of follow-up did not differ significantly between groups (14% with fcSEMS vs. 5% with plastic stents).

In a large meta-analysis of 1298 patients with benign biliary stenosis who were treated with fcSEMS, a lasting therapeutic success with complete regression of the biliary stenosis was achieved in 83% [72]. For the subgroup of patients with biliary stricture due to a chronic inflammatory process of the pancreas, there was a somewhat greater heterogeneity compared to postoperative benign bile duct strictures, but also comparable results. fcSEMS were as effective as multiple plastic stents but required fewer ERCPs. Thus, fcSEMS placement appears to provide an advantageous alternative to plastic stents in the management of benign biliary strictures. Exchange of single plastic stents should be undertaken at least every 3 months because otherwise occlusion of the stent may cause cholangitis. The exchange interval is less critical with the insertion of multiple stents and is much longer if fully coated metal stents are used. Those are patent for up to 9 months [73]; however, partial obstruction by sludge or stones often occurs.

The management of chronic bile duct obstruction after unsuccessful attempts of endoscopic treatment should be surgical. If there is an indication to treat cholestasis by surgery, a preoperative endoscopic insertion of a stent into the bile duct should only be undertaken if (i) surgery cannot be done promptly, or (ii) cholangitis is present.

A multicenter prospective randomized study examined the effect of preoperative endoscopic stent insertion into the CBD for mechanical cholestasis secondary to carcinoma of the head of the pancreas before pancreas resection. Preoperative drainage significantly increased the rate of complications (39% severe complications without drainage vs. 74% with drainage). Therefore, in the absence of cholangitis, bile drainage is not indicated if surgery can be performed promptly [74]. A short individual life expectancy of a patient, a high comorbidity, and a difficult, foreseeable technical feasibility of an operation (e.g., marked collateral circulation secondary to portal hypertension), are all in favor of an endoscopic treatment of bile duct obstruction.

Major Pancreatic Resection for Chronic Pancreatitis: Indication, Goals, and Limitations

Faik G. Uzunoglu and Jakob R. Izbicki

Department of General Visceral and Thoracic Surgery, University of Hamburg Medical Institutions, Hamburg, Germany

Definition of Chronic Pancreatitis

A multidisciplinary expert consensus proposed a new mechanistic definition of chronic pancreatitis (CP) in 2016 [1]. CP is defined as "a pathologic- fibro-inflammatory syndrome of the pancreas in individuals with genetic, environmental and/or other risk factors who develop persistent pathological responses to parenchymal injury or stress." Major international societies have adopted the mechanistic approach. It is based on a conceptual model with five stages ranging from A (at risk) to E (end-stage CP) (Fig. 63.1).

Timing and Goals of Major Pancreatic Resections

Based on the mechanistic approach, surgical therapeutic interventions need to take place in stage C (early CP) or stage D (established CP) rather than in stage E (end-stage of CP) with irreversible features and complications of CP.

Therefore, a potential surgical intervention needs to occur months after the initial acute pancreatitis event (early CP, stage C). To facilitate preventive and therapeutic interventions in time, it requires a multidisciplinary team (gastroenterologists, advanced endoscopists, radiologists, pancreatic surgeons, pain, and nutritional specialists), which initiates diagnostics and therapeutic interventions at the sentinel event, since up to 35% of patients with an initial episode of acute pancreatitis will develop CP within 3–8 years [2,3].

The basis of any intervention in time is an accurate diagnosis of early CP. The mechanistic definition includes a second part: "Common features of established and advanced CP include pancreatic atrophy, fibrosis, pain syndromes, duct distortion and strictures, calcifications, pancreatic exocrine dysfunction, and dysplasia." Therefore, the mechanistic definition does not require prominent imaging features to diagnose early CP. Unfortunately, a consensus for a definition of early CP or diagnostic criteria could not be established within the international working group in 2017 [4].

Until consensus is reached, potential surgical interventions remain based on imaging combined with patients' pain burden.

While computed tomography is the most appropriate baseline imaging modality for CP, it cannot exclude a CP or be used exclusively to diagnose early CP (stage C). Magnetic resonance cholangiopancreatography (MRCP) and secretin-stimulated MRCP are more accurate for detecting subtle changes in the early stages. The role of endoscopic ultrasound is limited to inconclusive MRCP results or (planned) therapeutic interventions [5]. ERCP should not be used for diagnostic purposes [6].

The conceptional model predetermines successful interventions as early as possible to prevent end-stage CP with fibrosis/sclerosis, exocrine and endocrine insufficiency, and chronic pain syndrome. The goal of surgical intervention in time can only be reached if the old paradigm "surgery is the last option" is abandoned. Surgery in an early stage of CP has the potential to achieve the main goals, namely, to mitigate disease progression, pain control without chronic opioid dependency, and restore quality of life [7,8], preserve exocrine function [9], prevent rather than manage local complications (bile duct or bowel obstruction, portal vein compression, splenic vein thrombosis, fistula, or pseudocyst and pseudoaneurysms/erosion of large vessels).

While the change of lifestyle and conservative treatment will often remain the first step, the period of medical pain management should be limited by the multidisciplinary team from the beginning due to the risk of opioid

dependency and the development of neuropathic pain [10]. Failure of conservative pain management should lead to discussing endoscopic and surgical options as equivalent options for first-line interventional treatment within the multidisciplinary team and the patient. The treatment advice should consider the following data: early surgery leads to more pain relief and less postoperative opioid use [9,11–14], multiple endoscopic interventions are associated with reduced success in terms of long-term pain relief after surgery [8], and 40–75% of CP patients will require surgery in the course of the disease [15]. Most recently, the randomized ESCAPE trial results support these findings [16]. The early surgery approach was superior, with lower pain scores over 18 months than the endoscopy first approach. Complete pain relief was achieved in almost 60% of the early surgery group vs. 40% in the endoscopy first group. One-third of patients in the endoscopy group were referred to undergo surgery because of failed endoscopic treatment.

Limitations of Major Pancreatic Resections

Although surgical intervention is a significant key to success in patients suffering from CP, some circumstances limit surgical options. In advanced stages of CP cachexia, severe malnutrition, and sarcopenia are often evident and associated with higher perioperative morbidity and mortality [17]. Accordant nutritional therapeutic options must be considered before surgery to obtain optimal surgical results. A complete portal thrombosis with portal hypertension is a relative contraindication for surgery. The risk of bleeding and perioperative complications is significantly increased in this subgroup of patients. Preoperative recanalization of the mesentericoportal axis with subsequent surgery should be limited to high-volume centers with accordant expertise [18–20].

Surgical Strategies Based on Morphological Characteristics

Surgical interventions need to be based on the following goals:

- Effective in terms of long-term pain management and local complications (restore quality of life);
- Preservation of maximum endocrine and exocrine function;
- Safety (low morbidity and mortality;
- Long-term sufficient drainage of the pancreatic duct.

Based on these goals, the primary surgical strategies and indications will be summarized and expanded upon in subsequent chapters. The recommendations are based on the international consensus guidelines published in 2019 [21]. Differing treatment strategies at the authors' institution are emphasized if indicated.

Chronic Pancreatitis with Enlarged Pancreatic Head without Strictures or Stones in Pancreatic Corpus and Tail

In patients with a morphology characterized by a solely enlarged pancreatic head (inflammatory mass) without pathologies in the pancreatic corpus or tail, a duodenum-preserving pancreatic head resection (DPPHR) may be the treatment of choice. All DPPHR procedures have the advantage of maintaining the physiological gastroduodenal passage and common bile duct continuity.

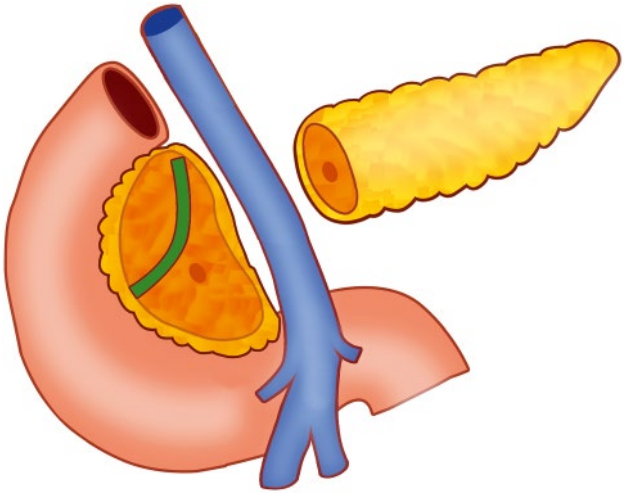

Figure 63.2 Beger procedure: subtotal resection of the pancreatic head with transection of the pancreas above the portal vein. *Source:* Faik G. Uzunoglu.

DPPHR variations in these patients consist of the Beger- or Berne procedure. The Beger procedure is characterized by a subtotal resection of the pancreatic head with transection of the pancreas above the portal vein (Fig. 63.2). The Berne procedure avoids a complete transection of the pancreas above the portal vein (Fig. 63.3). The inflammatory periportal fibrosis with or without portal vein thrombosis carries a high risk of bleeding complications that might be difficult to control.

An alternative to DPPHR variations is the (pylorus-preserving) pancreaticoduodenectomy. This procedure is often not the treatment of choice because of surrounding vessels' involvement by the pancreatic head's inflammatory mass. In terms of long-term pain relief, no differences are evident, as well as regarding morbidity, pancreatic fistula rate, or operative time. The DPPHR group was superior in quality of life, postoperative weight gain, and more exocrine function impairment within a systematic review and meta-analysis [22].

At the authors' institution, the (pylorus-preserving) pancreaticoduodenectomy is only the treatment of choice in uncertain cases with high suspicion of malignancy and if malignancy cannot be ruled out securely by frozen section analysis or in case of bowel obstructions that cannot be resolved sufficiently by DPPHR.

Chronic Pancreatitis with Dilated Main Duct with or without Enlarged Pancreatic Head

In patients with a morphology characterized by duct dilatation ≥5 mm with or without an enlarged pancreatic head, a modified DPPHR such as the Frey or Hamburg procedure may be the treatment of choice.

Like the Berne procedure, the Frey procedure does not include the division over the superior mesenteric portal vein. Still, it combines the DPPHR with a longitudinal opening of the pancreatic duct up to 1–2 cm from the splenic hilum (Fig. 63.4). While the Frey procedure is the treatment of choice for patients with main duct dilatation with an enlarged pancreatic head, sufficient data is lacking on whether the Frey procedure or solely the longitudinal opening of the pancreatic duct should be preferred in patients with standard size pancreatic head. If the surgeon's choice of treatment favors the longitudinal opening solely, it should be done in an extended manner within 1 cm of the duodenum to decompress the

complete pancreatic duct, including Wirsung and Santorini's ducts [23,24].

At the authors' institution the standard of care in patients with or without enlargement of the pancreatic head is the "Hamburg procedure" (Fig. 63.5). Like the Frey and Berne procedures, the division of the pancreas above the mesentericoportal axis is avoided. Still, comparable to the Berne procedure, the extent of the coring of the pancreatic head is customized to the individual morphology of the pancreas and extended, including the uncinate process if necessary. The extended coring of the pancreatic head, including the uncinate process compared to Frey, secures the bile duct decompression to the full extent and prevents a potential recurrence of common bile duct compressions. At the same time, decompression of the complete pancreatic duct system, including Wirsung and Santorini's ducts, is assured.

If, during the decompression of the intrapancreatic common bile duct, an injury to the intrapancreatic bile duct occurs, reinsertion of the distal common bile duct into the pancreatic resection cavity is frequently performed. Considering the high incidence of anastomotic strictures after reinsertion [25], this procedure has been abandoned at the authors' institution, and the DPPHR procedure is combined with a bilioenteric anastomosis.

Regarding the longitudinal opening of the pancreatic duct in the body and tail of the pancreas, the Hamburg procedure is characterized by a V-shaped opening of the main pancreatic duct instead of the solely longitudinal opening during the Frey procedure. The rationale here is the drainage of pancreatic duct side branches of second- and third order for securing long-term drainage of the pancreatic body and tail, especially in sclerosing (small duct) CP or extended calcifications of the pancreatic parenchyma in the pancreatic body and tail [26].

Chronic Pancreatitis with Isolated Left-Sided Strictures or Stones without Enlarged Pancreatic Head

In patients with left-sided symptomatic stones that are not reachable for endoscopic interventions, including extracorporeal lithotripsy, as well as in patients with left-sided strictures or complete duct disruption (e.g., after acute necrotizing pancreatitis) with patent pancreatic head and body, the longitudinal opening of the left-sided pancreatic duct (Partington and Rochelle) may be the treatment of choice (Fig. 63.6). Distal pancreatectomies should be avoided to prevent impaired exocrine function whenever possible.

At the authors' institution, the longitudinal opening is performed V-shaped. In selected cases and depending on the morphology of the pancreas, the senior author performs a stapled complete transection of the pancreas (if necessary, including a segmental resection) before the dilatated duct area followed by a V-shaped resection of the remnant left-sided pancreas with accordant drainage by a Roux limb. From the authors' point of view, the complete transection often allows a safer anastomosis to the left-sided pancreatic remnant. Indications for concurrent splenectomy in this setting include a perisplenic pseudocyst, splenic vein thrombosis, or fibrotic encasement of the splenic vessels.

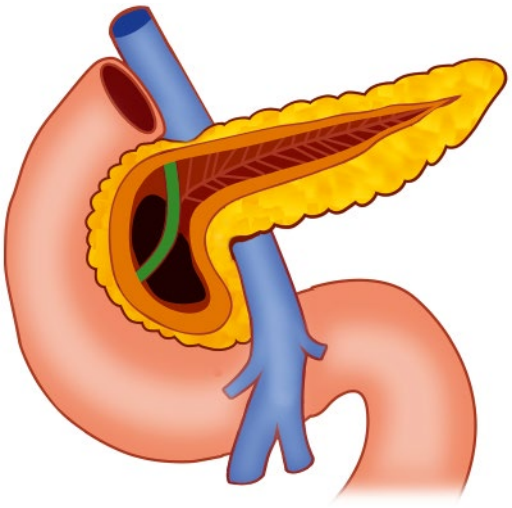

Figure 63.5 Hamburg procedure: avoidance of complete transection of the pancreas above the portal vein, extended coring of the pancreatic head, including the uncinate process. V-shaped opening of the main pancreatic duct for drainage of side branches of second- and third order for securing long-term drainage of the pancreatic body and tail. *Source:* Faik G. Uzunoglu.

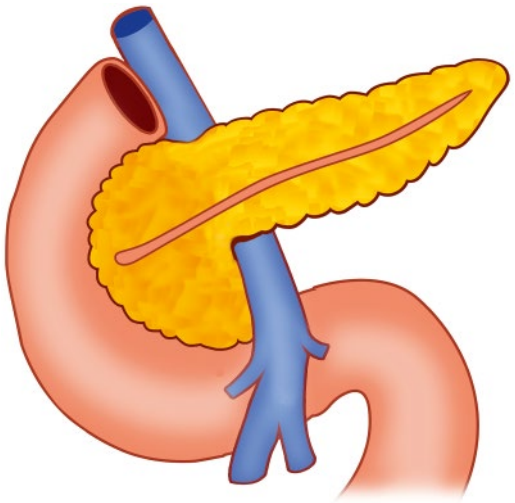

Figure 63.6 Extended Partington and Rochelle: longitudinal opening of the left-sided pancreatic duct within 1 cm of the duodenum to decompress the complete pancreatic duct, including Wirsung and Santorini's duct. *Source:* Faik G. Uzunoglu.

Pancreatic Drainage Procedures: Techniques and Results

Ulrich F. Wellner, Dirk Bausch, and Tobias Keck

Department of Surgery, University Medical Center Schleswig-Holstein, Campus Lübeck, Germany

Introduction

Compared to the general population, chronic pancreatitis (CP) is associated with a fourfold increase in mortality [1] and an increased risk for pancreatic malignancy. About 5% of patients with CP will develop pancreatic cancer over 20 years [2]. Its progressive inflammatory destruction of the pancreatic parenchyma is usually accompanied by intractable pain, a loss of exocrine and endocrine pancreatic function, clinically evident as malabsorption and pancreatogenic diabetes.

The pathogenesis of pain in CP is likely multifactorial. One potential mechanism may be increased intraductal pressure and obstruction of the pancreatic ductal system. Inflammation itself together with alterations in pancreatic nerve fibers, including an increase in nerve fibers and neurogenic inflammation may also contribute to the typical pain commonly associated with CP. Changes in the central nervous system and alterations in central pain processing may also contribute to pain associated with CP. The characteristic abdominal pain often leads to impaired social and work life due to recurrent hospitalizations [3].

Currently, endoscopic or interventional treatment is considered the first step in the treatment of patients with CP. Endoscopic treatment that relieves the pancreatic ductal system (endoprothesis, stone extraction, extracorporeal shock wave lithotripsy, or ductal dilatation) improves pain for up to 1 year [4]. Multiple interventions improve pain in about 65% of the cases and reduce the rate of patients requiring surgical intervention [5].

However, stent replacement often has to be performed 3-monthly and may require multiple hospital admissions [6,7]. After unsuccessful endoscopic treatment, about 49% of the patients still require surgery within 1 year [8]. While endoscopic duct drainage may provide long-term success in the presence of isolated proximal duct stenosis and in the absence of an inflammatory mass of the pancreatic head and calcifications, surgery is superior to endoscopic therapy in the latter case [9] and may also be more cost-effective [10].

Moreover, early surgical intervention may also prevent disease progression, preserve pancreatic function, and improve long-term pain control [9,11–13]. The initial findings of the Cahen study have recently been validated in another randomized trial conducted in the Netherlands (ESCAPE trial): patients with large duct disease and opioid-dependent pain of less than 6 months' duration were randomized to receive upfront surgery versus endoscopic treatment. At 18 months follow-up, there was significantly better pain control in the upfront surgery group (58% vs. 39% pain relief), with lower number of interventions, comparable pancreatic function as well as 0% mortality [14].

Indication for Surgery

The most common indication for surgery for CP is intractable pain despite pharmacological and/or endoscopic intervention. Other indications for surgery are local complications, such as duodenal or biliary stenosis, symptomatic pseudocysts, pancreaticopleural fistula, a disconnected pancreatic duct, pancreatogenic ascites, or suspicion of neoplasm. All procedures attempt to reduce pain and resolve organ complications while preserving exocrine and endocrine function. Their long-term efficacy is commonly evaluated by the restoration of quality of life and successful rehabilitation. Three distinct groups of procedures can be employed to treat CP: drainage procedures, procedures combining drainage and resection, and resecting proce-

dures. The choice of procedure depends on the morphologic features of the pancreatitis. Drainage combined with resection of the pancreatic head (Beger procedure [15]), Frey procedure [16]) is commonly chosen if an inflammatory mass of the pancreatic head is present, resecting procedures (pylorus-preserving pancreaticoduodenectomy, Whipple procedure) are used if malignancy is suspected. The majority of patients with CP (85%) have an inflammatory mass of the pancreatic head and thus require drainage combined with resection or resection of the pancreatic head [17] (Fig. 64.1). However, drainage procedures are the procedure of choice in patients with a dilated pancreatic duct (≥5 mm) without an inflammatory mass [18]. Another indication for surgical drainage may be cavernous transformation of the portal vein with collaterals in the case of long segment portal vein stenosis. However, short segmental portal vein or mesenterico-portal vein stenosis with portal hypertension may also be alleviated during pancreatic head resection by decompressing the stenosis [19]. Resection of the pancreatic head is even possible after interventional recanalization of the portal vein for nonfixated portal vein thrombosis. Drainage procedures are thus not mandatory in this situation [20].

Drainage Procedures

The first drainage procedure of the pancreas in humans was performed in 1911 through transcutaneous catheter placed in the pancreatic duct [21]. The procedure provided pain relief and the patient survived for 30 years. More than 50 years later, the procedure was modified and a distal pancreatectomy, splenectomy, and pancreaticojejunostomy were performed [22]. The procedure was further refined as a distal pancreatectomy and side-to-side pancreaticojejunostomy[23]. The latero-lateral panceaticojejunostomy still in use today was first described in 1960 [24].

A Partington–Rochelle procedure (Fig. 64.2) is comprised of an incision of the pancreatic duct at the anterior surface of the pancreas from the tail to the head of the pancreas. Calculi in the pancreatic ducts can then be removed and segmental stenosis can be relieved. The procedure is completed by a Roux-en-Y jejunal limb sutured side-to-side to the pancreatic duct [24].

Drainage procedures are associated with low morbidity and mortality rates (about 1%). However, drainage is inferior to resection regarding pain management and complication management [18,25–36] (Fig. 64.3).

As a hybrid procedure with partial resection of the pancreatic head, the Frey procedure is often also considered a drainage procedure. It is comprised of an excoriation of the pancreatic head combined with an incision of the pancreatic duct at the anterior surface of the pancreas to the tail of the pancreas (Fig. 64.4). The procedure is completed by a Roux-en-Y jejunal limb sutured side-to-side to the excoriated pancreatic head and pancreatic duct [16]. Compared to the Partington–Rochelle procedure, the Frey procedure improves the long-term outcome. Compared to other resection procedures, the outcome achieved by the Frey procedure is equivalent regarding pain control, quality of life, and exocrine and endocrine organ function [34,37–40].

A rare form of CP, termed "small duct disease" affects the whole organ. It is not associated with a dilated

pancreatic ductal system and may easily be misdiagnosed as autoimmune pancreatitis. Treatment of choice for this small duct disease is the longitudinal V-shaped excision of the ventral pancreas. The procedure combines extensive drainage with a limited resection [41]. This drainage procedure may provide long-term pain relief and an improved quality of life in the majority of patients. Compared to V-shaped excision, resection may not be as effective in the treatment of small duct disease [42].

Conclusion

Taken together, pure drainage procedures such as the Partington–Rochelle procedure are often not sufficient to provide acceptable pain and complication control due to a frequently observed inflammatory mass of the pancreatic head. In the absence of an inflammatory mass, they provide good results with low morbidity and mortality. In the presence of an inflammatory mass, hybrid procedures such as the Frey procedure or V-shaped excision are as effective as resection.

Introduction

Chronic pancreatitis (CP) is a pathologic fibro-inflammatory syndrome of the pancreas in individuals with genetic, environmental and/or other risk factors, who develop persistent pathologic responses to parenchymal injury and stress [1]. Common features of CP include pancreatic atrophy, tissue fibrosis, upper abdominal pain, duct distortion and strictures, and in the late course of the disease, inflammatory head mass, calcifications and pancreatic duct stones, duodenal dystrophy, functional exocrine insufficiency, diabetes mellitus, and cellular dysplasia.

The mechanistic definition of CP, recently published as the result of an international proposal, reflects the complex nature of CP. Alcohol abuse and cigarette smoking are the most frequent causes of CP. After a preclinical period of up to 12 years, the majority of patients develop abdominal complaints and upper abdominal pain as first signs of the disease. In the late stage, local complications are caused by the progressive inflammatory process, enhanced by alcohol consumption and cigarette smoking. Patients referred for surgical treatment suffer severe abdominal pain; 30–50% show alcoholic CP exhibiting an inflammatory mass in the head of the pancreas, frequently causing common bile duct (CBD) obstruction [2,3]. Infrequently, severe obstruction of the duodenum, portal vein compression or thrombosis and splenic vein occlusion are clinically relevant. Pathomorphologically, main duct stenosis with prestenotic duct dilation and side branch duct stenoses are observed (Table 65.1). In terms of the natural history of CP, see Chapter 40; for early stage CP, see Chapter 50; for the epidemiology and pathophysiology of alcoholic CP, see Chapter 48; and for strategies for surgical treatment, see Chapter 63.

Are Duct Stenting and Endoscopic Interventions an Alternative to Surgery?

Duct stenting, endoscopic dilatation of pancreatic main duct stenosis and endoscopic stone extraction for obstructive CP, have been reported by a number of recent studies with good results. However, sphincterotomy and stenting of the pancreatic main duct is considered a temporary treatment. The risk of stent occlusion and migration and the need for long-term control of upper abdominal pain are the limitations of the interventional endoscopic treatment modalities. Data from prospective, randomized mono-institutional trials comparing endoscopic therapy with surgical treatment have been published [9,10]. Short-term pain relief was similar in both groups. The long-term outcome after a 1- to 3-year follow-up revealed major advantages for the surgical treatment in regard to pain control and frequency of rehospitalization compared to interventional stenting.

Who Benefits from Surgical Treatment?

Surgery for CP is essentially a palliative treatment. The primary goals of surgical treatment for CP are [1] long-term pain control, and [2] control of CP-associated complications of adherent tissues. Upper abdominal pain refractory to medical treatment in combination with local complications is the most frequent setting for surgical treatment (Table 65.2) [3]. Preservation of exocrine and endocrine pancreatic functions are secondary but equally important goals of surgical treatment. Most patients with CP are under

- Pancreas divisum after failure of endoscopic treatment

55 years and professionally active [4]. Social and occupational rehabilitation and improvement of the quality of life are additional primary goals for the long-term outcome.

Kausch-Whipple Resection or Hemipancreatectomy Still Standard Treatment for Chronic Pancreatitis?

Currently, pancreaticoduodenectomy (PD), left or distal hemipancreatectomy and total pancreatectomy are still applied for CP. The disadvantages of these major pancreatic resections are (i) unnecessary sacrifice of pancreatic and peripancreatic biliary and gastroduodenal tissues, and (ii) the surgery-inherent loss of duodenal and pancreatic tissue is associated with increased impairments of the endocrine and exocrine pancreatic functions in the long-term outcome. New onset of diabetes mellitus and exocrine insufficiency have been overwhelmingly documented after PD and hemipancreatectomy [11–23]. Long-term observation showed that patient survival was shorter after duodenopancreatectomy for CP compared to an organ-preserving surgical procedure [24].

Indication and Rationale for Duodenum-Preserving Pancreatic Head Resection

Surgical treatment of CP is presently dominated by organ-preserving surgical procedures. Introduced by Partington–Rochelle [25], the intestinal drainage procedure of the pancreatic main duct and the duodenum-preserving subtotal pancreatic head resection and their modifications have the advantages of tissue sparing and maintenance of pancreatic functions [26]. Based on contrast-enhanced CT, MRI and MRCP, the majority of pathomorphologic changes of CP are observed predominantly in the pancreatic head, frequently associated with an inflammatory mass and obstruction of the CBD. Infrequently, the inflammatory tumor in the pancreatic head causes portal vein and superior mesenteric vein compression and obstruction of the duodenum. To resolve these complications, resection of the pancreatic head is recommended. Duct drainage procedures in CP are only indicated in the subgroup of patients with pancreatic main duct stenosis and dilatation extended into the duct of the body and tail. With regard to long-term pain control, duct drainage procedures without resection of the pancreatic head are associated with a reappearance of an abdominal pain syndrome in about one-third of patients observed after a >5-year follow-up [27]. A duct drainage procedure in CP is considered unnecessary in patients with a dilated body-tail duct without duct obstructions when the pancreatic head is resected. Long-term follow-up observations after PD and DPPHR have shown a long-lasting pain control after head resection without an additional duct drainage procedure [28,29]. The effectiveness of duodenum-preserving pancreatic head resection has been proved, whereby randomized controlled trials (RCT) and long-term observations of 5–10 years showed completely pain-free patients in 80–90% of cases. For patients with an inflammatory head mass who were treated with a duct drainage procedure without subtotal pancreatic head resection, a risk persists for the development of a biliary stenosis in the long-term follow-up with the need for biliary stenting, respectively re-surgery.

Surgical Technique of Duodenum-Preserving Total Pancreatic Head Resection for Chronic Pancreatitis

DPPHR comprises three different surgical steps:

1) Exposition of the pancreatic head with identification of the portal vein, respective inferior mesenteric vein, and the supraduodenal CBD; tunneling of the pancreatic neck in front of the portal vein.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

2) Subtotal resection of the pancreatic head to conserve the intrapancreatic CBD.
3) Reconstruction with an excluded jejunal loop, executing two pancreatic anastomoses.

Steps (1) and (3) are almost identical to the surgical steps performed in the Kausch-Whipple procedure.

An extensive Kocher maneuver should be avoided to preserve the vessels on the dorsal side of the pancreatic head. The anterior gastro-duodenal artery is identified and ligated near the common hepatic arteries. The posterior-superior branch of the pancreaticoduodenal artery and the inferior-anterior pancreaticoduodenal artery should be carefully preserved. Subtotal resection of the pancreatic head is performed from the ligamentum hepatoduodenale along the intrapancreatic segment of the CBD, including the uncinate process (Figs. 65.1 to 65.3). Bleeding vessels arising in the transected tissue are immediately sutured (Fig. 65.4). Preservation of the dorsal capsule of the pancreatic head and the dorsal branch of the gastroduodenal and pancreaticoduodenal vessels are recommended to maintain sufficient perfusion of the wall of the duodenum and papilla. Reconstruction of the gastrointestinal tract is performed with an excluded jejunal loop (Fig. 65.5). Two modifications of the duodenum-preserving pancreatic head resection are presently in use. In patients displaying a prepapillary CBD stenosis, which persists due to an inflammatory process in the wall of the CBD, after subtotal head resection, an additional biliary anastomosis by an incision of the CBD is executed [30] (Fig. 65.5).In patients who show multiple stenosis and dilations of the main duct in the body and tail, the pancreatic main duct is opened longitudinally on its ventral surface extending toward the tail of the pancreas. A side-to-side anastomosis is executed in addition to the head resection [31].

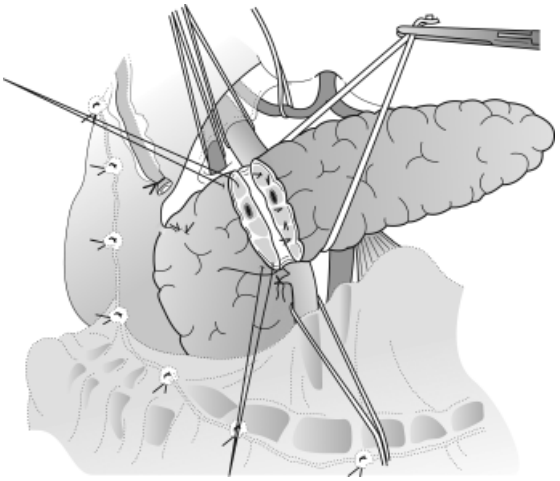

Figure 65.1 Duodenum-preserving pancreatic head resection after tunneling of the portal vein behind the pancreas. Resection line is the duodenal side of the portal vein.

Berne Modification of the Beger Procedure

In 2001, Gloor et al. published results of a small institutional series of subtotal pancreatic head resections renouncing tunneling of the portal vein and sparing transection of the pancreatic neck [32]. Using pancreatic

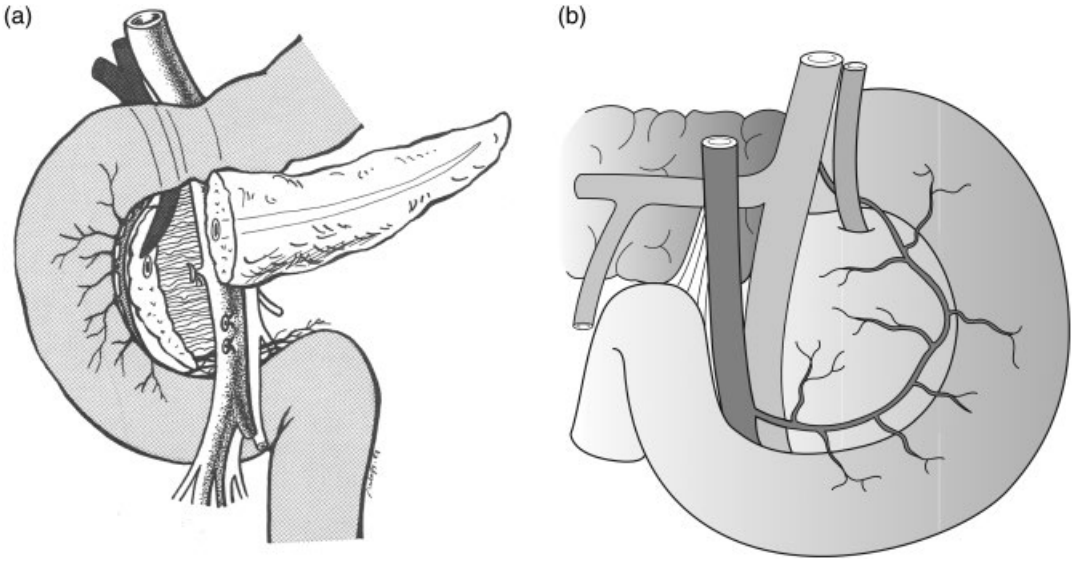

Figure 65.2 (a) After finishing the subtotal pancreatic head resection, a shell-like rest of the pancreatic head along the duodenal wall. Bleeding vessels, which are frequently closed by single suturing using five O-sutures. (b) The dorsal capsule of the pancreatic head is preserved to maintain blood flow to and from the duodenal wall. The dorsal pancreaticoduodenal arcades and inferior pancreaticoduodenal artery are preserved.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 65.3 Reconstruction of the upper jejunal loop after subtotal resection of the pancreatic head requires exclusion of the first jejunal loop and creation of an end-to-side duct-to-mucosa anastomosis between the pancreatic neck and the jejunum (two-layer anastomosis). Anastomosis between the shell-like remnant of the pancreatic head and the excluded jejunal loop (end-to-side anastomosis) is also performed. A Roux-en-Y anastomosis between the excluded jejunal loop and the first jejunal as side-to-end anastomosis is included.

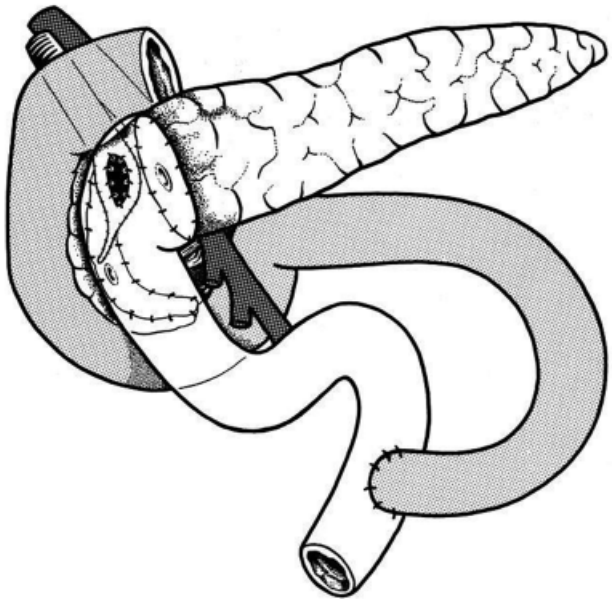

Figure 65.4 In case of extended narrowing of the intrapancreatic segment of the common bile duct caused by an inflammatory process in the wall of the common bile duct, an internal biliary anastomosis is additionally executed by incision of the prepapillary common bile duct of 10–12 mm.

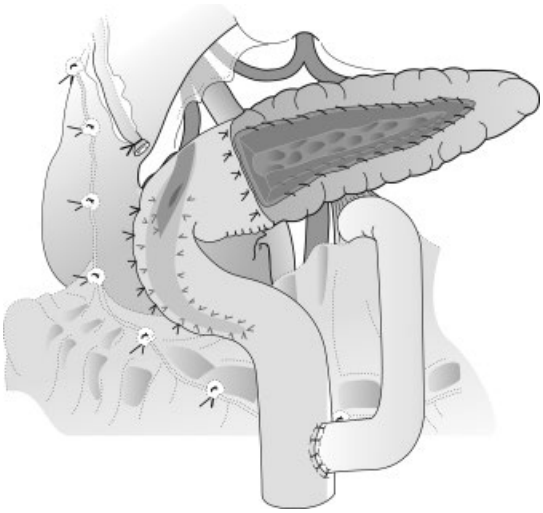

Figure 65.5 Where the pancreatic main duct shows multiple duct stenoses and dilatations, duct drainage of the pancreatic main duct from the head to the tail is additionally applied by a side-to-side anastomosis with the excluded jejunal loop.

tissue dissection devices, a subtotal resection of the pancreatic head between the pancreatic neck at the level of the intrapancreatic course of the CBD is achieved. The subtotal coring-out resection of the pancreatic head and decompression of the intrapancreatic CBD are the main surgical goals of the DPPHR Berne modification. The restoration of the pancreatic secretion flow into the upper GI tract is achieved by an anastomosis with an excluded jejunal loop and the pancreatic tissue along the tissue resection line. This technique avoids a second anastomosis between jejunal loop and the shell-like pancreatic head remnant as is recommended for the subtotal DPPHR. The Berne modification is associated with the risk of postpancreatectomy bleeding due to the extended pancreatic resection surface. Additionally, the incomplete, partial pancreatic head resection does not effect a decompression of the intrapancreatic CBD, leading to biliary bile flow obstruction into the duodenum.

Early Postoperative Course

Early severe postoperative complications are infrequent (Table 65.3). Severe, surgery-related complications are <10% according to Clavien-Dindo III. Local bleeding, which appears as intestinal blood loss, caused by arterial leakage from the shell-like rest of the pancreatic head and anastomotic leakage, which appears as evacuation of intestinal content into the drainage bag, is observed in <2% of cases. Severe intestinal bleeding, leakage of the pancreaticojejunostomy and surgical-side infection around the pancreatic head are reasons for reintervention [26]. Between the second and fifth postoperative days, patients

are on regular oral nutrition (Table 65.4). The glucose metabolism is maintained at the preoperative level up to the fifth postoperative year (Table 65.4). When measuring the C-peptide and insulin response 3–36 months postoperatively after intravenous and oral glucose load, they remained at the reoperative level. However, the concentration of glucagon and pancreatic polypeptide (PP) displayed a highly significant decrease after stimulation [34–36].The loss of glucagon and PP delivery into the blood explains the observation that up to 10–12% of patients experienced a postoperative improvement of the disrupted glucose metabolism, because both hormones are produced predominantly in the endocrine tissue of the pancreatic head.

Long-Term Outcome after Duodenum-Preserving Pancreatic Head Resection

After a median observation period of 5.7 years and a follow-up rate of 94%, control of pancreatic pain is complete and long-lasting in approximately 90% of cases (Table 65.5). In terms of pain and attacks of pancreatitis, DPPHR changes the natural course to a silent disease. Preoperatively, each patient had 2.7 hospitalization periods, whereas after a median follow-up of 5.7 years, only 9% of the patients experienced a rehospitalization. Due to the persistent destruction of the functional parenchyma of the pancreas inherent in CP, the frequency of diabetes mellitus is increasing as well as the level of exocrine insufficiency [37–39]. Major advantages of duodenum-preserving subtotal pancreatic head resection for CP are conservation of the duodenum and the CBD and temporary maintenance of the endocrine pancreatic functions. More than five RCT have been published comparing DPPHR with Kausch-Whipple duodenopancreatectomy, with DPPHR superior in terms of postoperative morbidity, maintenance of glucose metabolism, an absence of delayed gastric emptying, and a low frequency of rehospitalization [40–45] (Table 65.6).

The Frey Procedure—an Alternative Surgical Approach for all Patients with Chronic Pancreatitis?

In 1987, Frey et al. published a technique for CP in six patients; the authors recommended a coring-out technique of ventral pancreatic head tissue combined with longitudinal pancreaticojejunostomy for CP [46]. In 1994, Frey propagated a variation of the LR-LPJ procedure, extending the coring out to the dorsal part of the pancreatic head, which results in a partial head resection, but left the intrapancreatic segment of the CBD predominantly embedded by pancreatic tissue. The Frey procedure, taking out some tissue ventrally from the pancreatic head, is rather a modification of the Partington–Rochelle duct drainage procedure. When

performing the Frey procedure as a subtotal pancreatic head resection in CP, the long-term outcome is similar to the DPPHR [47]. However, in many institutions that perform a duodenum-preserving resection in CP by coring-out of the pancreatic head tissue, it is executed as a partial ventral pancreatic head resection. The long-term outcome regarding pain control after ventral coring-out of pancreatic head tissue is reestablishment of upper abdominal pain in approximately one-third of the patients [29]. An additional risk of the Frey procedure lies in the incomplete decompression of the CBD due to partial ventral coring-out of pancreatic head tissue, whereby the patient will postoperatively suffer from cholestasis and attacks of cholangitis due to persistence or reappearance of the duct compression by pancreatic tissue mass. Re-surgery after the Frey procedure is a well-documented indication for redo-surgery because of persistence of biliary stenosis [48,49].

Results of RCT Comparing PD and DPPHR for Chronic Pancreatitis – The ChroPac Trial

The results of the prospective, randomized, multi-institutional ChroPac trial published in 2017, reported clinical evidence that favors PD for CP [51]. However, the evidence of the ChroPac trial results is limited owing to the striking heterogeneity of the compared procedures (PD group included Whipple or PPPD and DPPHR group included three different procedures: Beger, Berne, and Frey) [51]. Furthermore, 8 of 18 participating surgical institutions contributed only 1 patient per year in the 4-year allocation period of the trial. The randomization protocol resulted in an unusually frequent accumulation of very advanced CP in the DPPHR group. Metabolic data of pancreatic functions in the ChroPac study were not determined, but taken from the patients' records at the participating institutions. The results of the four mono-institutional prospective RCT comparing PD and DPPHR for CP were based on 170 patients following DPPHR and 160 patients following PD [40–42,44]. These trials provided high-quality evidence of the advantages of DPPHR

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. for CP regarding a significantly lower frequency of early postoperative, severe complications, an absence of surgery-associated, early postoperative endocrine and exocrine metabolic morbidity, and postoperative reestablishment of an adequate quality of life. These results, albeit derived from mono-institutional RCTs underline the advantages regarding early surgery-related morbidity and late postoperative maintenance of endocrine and exocrine pancreatic functions following DPPHR compared to PD.

Long-term follow-up in median 15 years after DPPHR and PPPD for CP revealed a significantly reduced survival when PPPD was used for CP compared to DPPHR Hamburg modification. Patients initially included in a prospective, randomized controlled clinical trial had a median survival after PPPD of 11.3 years, whereas following DPPHR the median survival was 14.5 years. The highly significant survival benefit after application of a modified duodenum-preserving pancreatic head resection for CP was clearly associated to the maintenance of the endocrine and exocrine pancreatic functions due to duodenum preservation [24].

Summary

Duodenum-preserving resection of the head of the pancreas is a low-risk procedure for patients with CP, particularly for those who have developed an inflammatory mass in the pancreatic head. Subtotal resection of the pancreatic head does not result in a significant reduction of the exocrine and endocrine functions of the pancreas. Owing to the limited nature of the intervention, hospital and late mortality rates are low. More than 80% of the patients with CP have experienced long-lasting relief of pain after duodenum-preserving head resection. For patients with a stenosis of the intrapancreatic common bile duct, an internal biliary anastomosis establishes long-lasting normal bile flow. For patients with multiple duct stenosis in the left pancreas, duct stones, calcifications and duct dilations, an additional pancreaticojejunostomy, additional to subtotal pancreatic head resection, relieves recurrent attacks of pancreatitis and restores pain-free survival and quality of life.

> Emil Theodor Kocher (1841–1917)

Introduction

Chronic pancreatitis (CP) is a difficult disease with a common progression to pancreatic exocrine insufficiency, diabetes mellitus, and narcotic dependence due to chronic pain over years to decades. Typical medical therapies include pancreatic enzyme supplementation and other medical therapy, interruption of pancreatic toxins (especially alcohol), and endoscopic interventions. While this is successful in many patients, there remains a subset of patients without adequate responses to medical and endoscopic interventions.

Typical surgical interventions have relied on the ability to either extirpate the segment of pancreas most affected by the CP, or by a variation of pancreatic duct drainage. These interventions have been proven to be effective in appropriately selected patient populations [1,2]. However, there are several subgroups of patients that are not as amenable to classical surgical interventions, including those with so-called minimal change or small duct pancreatitis, and those with familial disease, including *SPINK1*, *PRSS1*, *CTRC*, *CFTR*, and other mutations predisposing to CP.

In 1977, the first total pancreatectomy with islet autotransplantation procedure was performed by D. Sutherland and colleagues at the University of Minnesota, in part to better understand isolated pancreatic islet function after transplantation into the portal venous system. Interestingly, this operation was successful both in resolving the chronic pain from CP, and in long-term preservation of islet cell function [3,4]. Since that time, an experimental procedure performed at one institution has become a frequently performed operation at more than two dozen centers across the world with more than 1000 cases reported [5].

This procedure is unique in several ways. In addition to having a surgeon skilled in performance of one of the more challenging cases in surgery today, the key component of a successful procedure requires the presence of an experienced islet cell isolation facility, and a team of caregivers experienced in selecting and caring for the patient's issues such as diabetes mellitus, malnutrition, pain management, and exocrine dysfunction through surgery and recovery. Unlike typical transplantation, patients receiving islet autotransplantation do not require immunosuppression as they are receiving their own tissue. Given these components, mortality from this operation is <1% in reported series, but with morbidity expected after a pancreatectomy (up to 60%) [6].

Evaluation of the Patient with Chronic Pancreatitis for Surgical Intervention

The primary goal of performing a total pancreatectomy and islet autotransplantion is to provide relief of pain. An appropriate evaluation of the patient provides information about how best to develop an individualized treatment plan for each patient. Components of a typical evaluation for patients with CP considering surgery involve historical review (looking for pancreatic interventions and histopathology), imaging, and focused laboratory testing to evaluate markers for and etiology of CP, pancreatic exocrine and endocrine function (Table 66.1). Tumor markers should be considered, especially in older patients, to evaluate the possibility of

cancer as an etiology of pancreatitis. Other causes of chronic abdominal pain should be considered in each patient and investigated as appropriate. Many younger patients without obvious etiology should receive genetic counselling and testing. Evaluation by a medical psychologist is frequently helpful as interventions are considered.

Decision-Making Process

Candidates for TPIAT at our institution are evaluated and discussed after evaluation by a multidisciplinary group including gastroenterology, surgery, endocrinology, nurse coordinators, health psychology, genetics, dietetics, social services, and pain management. Our approach to interventions follows Fig. 66.1, with therapy tailored to the individual patient. Many patients will benefit from a medical or endoscopic intervention. In those patients with calcifications and dilated duct, a drainage procedure such as a Frey or Beger procedure are often offered, as recovery is shorter and long-term outcomes in properly selected patients are good [2].

Many patients who have failed medical or endoscopic interventions have small-duct or minimal-change chronic pancreatitis (MCCP). This disease is characterized by chronic inflammatory destruction of the gland with subsequent exocrine/endocrine dysfunction and persistent abdominal pain without main duct dilation [7]. In the setting of small duct/minimal change disease total pancreatectomy represents the only valid surgical option for the treatment of pain [8,9]. Additionally, patients with genetic/familial disease are more likely to develop recurrent or progressive disease [10].

Patients who are being considered for a TPIAT meet the criteria in Table 66.2 [11], with proven pancreatitis, a significant effect on lifestyle, no reversible cause of pancreatitis, failure to respond to appropriate medical and endoscopic management, and adequate islet cell function.

There are a number of contraindications to this procedure, which include active drug abuse or alcoholism (we require 6 months of sobriety), active cardiac and respiratory disease with high perioperative risk, poorly controlled psychiatric disease, and inability to comply with postoperative care [16]. Additionally, pancreatic cancer or diffuse neoplasm and preexisting liver disease, including cirrhosis, portal hypertension or portal vein thrombosis are contraindications for major pancreatic resection or intraportal islet transplant [12,13]. Finally, patients with diabetes mellitus without C-peptide response will receive poor islet cell yields and poor postoperative graft function so TP alone is offered without the IAT [14].

A total pancreatectomy with islet autotransplantation is performed for management of a patient's pain. Previous learning has suggested that the pain from CP may "burn out" or resolve over 1–2 decades, although recent evidence suggests that this may not be the case [15]. A thorny issue is the question of when to intervene with surgery for patients suffering from chronic pain due to pancreatitis. A number of groups have investigated this

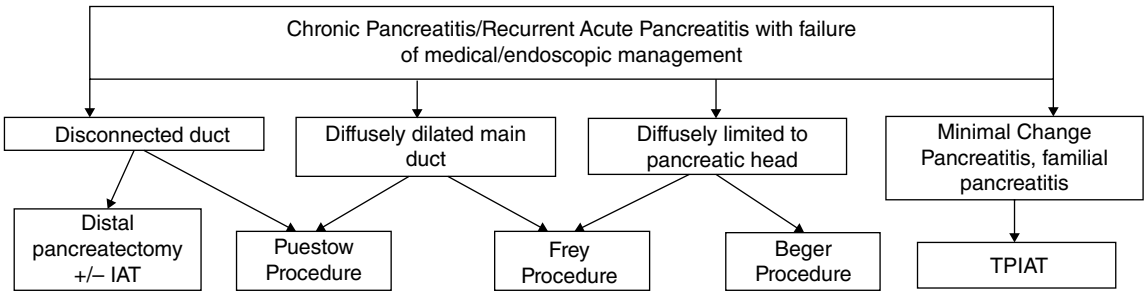

Figure 66.1 Decision tree for patients who have failed nonsurgical treatment for acute recurrent or chronic pancreatitis. TPIAT: total pancreatectomy with islet autotransplant.

Table 66.2 University of Minnesota criteria for total pancreatectomy and islet autotransplantation (must fulfill 1–5).

1) Diagnosis of chronic pancreatitis, based on chronic abdominal pain of ≥6 months duration and at least one of the following:
   - Pancreatic calcifications on computerized tomography scan.
   - At least two of the following: ≥4/9 criteria on EUS, compatible ductal or parenchymal abnormalities on secretin MCRP; abnormal endoscopic pancreatic function tests (peak HCO_2 ≤ 80 mmol/L).
   - Histopathology confirmed diagnosis of chronic pancreatitis.
   - Compatible clinical history and documented hereditary pancreatitis (e.g., *PRSS1* gene mutation).
   - History of recurrent acute pancreatitis (more than one episode of characteristic pain associated with imaging diagnostic of acute pancreatitis and/or elevated serum amylase or lipase greater than three times upper limit of normal).
2) At least one of the following:
   - Daily narcotic dependence
   - Pain resulting in impaired quality of life, which may include: inability to attend school, recurrent hospitalizations, or inability to participate in usual, age-appropriate activities
3) Complete evaluation with no reversible cause of pancreatitis present or untreated
4) Failure to respond to maximal medical and endoscopic therapy
5) Adequate islet cell function (nondiabetic or C-peptide positive)

MRCP: magnetic resonance cholangiopancreatography.
Source: Adapted from [11].

question, and repeated data suggests that outcomes after surgery for pancreatitis (including TPIAT and other operations) are improved with duration of chronic pain of 3 years or less [16,17].

Islet Cell Laboratory

The critical nature of an effective islet cell laboratory cannot be overstated. The presence of at least partial graft function is critical to maintain goal glycemic control and reduce glycemic variability, and insulin independence is associated with better quality of life after TPIAT [18]. Islet laboratories with significant annual experience have better islet yields on long-term graft function than those who do fewer isolations [19].

An important distinction in the setting of islet autotransplantation is that the US Food and Drug Administration does not consider these islets a manufactured biologic product. This requires processing of the islets under current Good Tissue Practice but not the more stringent current Good Manufacturing Practice regulations. In this setting, the goal of processing islets is to maximize islet yield, and not purity.

For the islet isolation step, after removal the whole pancreas is taken immediately to the islet facility, where it undergoes enzymatic and mechanical digestion to separate the pancreatic islets from acinar and pancreatic ductal tissue. Digestion is aided by use of the Ricordi Chamber, which enhances exposure of the pancreatic tissue to digestive enzymes [20]. The isolated islet tissue is returned to the operating room where islets are infused into the portal vein. Significant recent advances have been made in use of tailored enzyme preparations to enhance optimized islet isolation [21].

Unsurprisingly, there are far fewer facilities that have the manufacturing resources to perform islet isolation than there are that have skilled pancreatic surgeons. To address this issue, a number of centers have explored distant processing of the pancreas at a core facility with return of the isolated islets for infusion to the operative site. While time from removal of pancreas to infusion of islet is typically 8–10 hours longer, graft function results in these studies have been roughly comparable to those where pancreas was processed locally [22,23].

The Operation: Unique Features

The operation of total pancreatectomy with islet autotransplant is essentially a total pancreatectomy with duodenectomy (plus/minus distal gastrectomy) with a splenectomy. Although some institutions advocate a splenic-preserving procedure, because of the concern for affecting blood flow to the pancreas during surgery and the concern for postoperative sinistral portal hypertension with resultant gastric varices, we typically perform a splenectomy at the same setting. Patients should therefore be vaccinated preoperatively against *Streptococcus pneumoniae*, *Hemophilus influenzae*, and *Neisseria meningitidis* to minimize the likelihood of developing potentially lethal post-splenectomy sepsis. Appropriate vaccination strategies for these organisms change on a regular basis, with the most current guidelines typically available on the Centers for Disease Control and Prevention website [24]. Vaccination has been shown to significantly reduce the risk of post-splenectomy sepsis [25].

Another variation in patients undergoing pancreatectomy for islet cell isolation is the approach to preserve pancreatic blood supply to decrease warm ischemia time. In this case, the splenic artery and vein and gastroduodenal artery are identified, isolated, and preserved until the final dissection is complete. Typically these vessels are then ligated along with the common bile duct and uncinate process to complete the resection. The pancreas is immediately placed in a basin with iced saline where the duodenum is excised, excess peripancreatic

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

tissue is removed, and the gland is exsanguinated to facilitate enzymatic digestion. The gland is then sent to the islet cell laboratory for processing.

One controversy is whether to perform pylorus preserving or a standard distal gastrectomy during the resection. It is argued that delayed gastric emptying is shorter in those undergoing a classical resection, and that the risk of postoperative dumping syndrome is lower in those with pylorus-preserving resection. One of the outcomes awaited in the POST trial (a prospective, multicenter observation trial of outcomes after TPIAT) is related to this variation in care [26].

Islet processing can take from 5 hours for an islet laboratory co-located with the patient to up to 24 hours in a setting where islets are processed at a distant site. Another variation is how to manage the delay. There are a number of management techniques described. A common approach is to keep the patient in the operating room under anesthesia for the period of time that islets are being processed, infusing islets, then completing closure. Other described approaches include temporary cannulation and closure with removal of the catheter after infusion, percutaneous placement of catheter by IR into the portal system with infusion, or a return to OR for operative infusion of islets (the typical approach for centers utilizing remote processing of islets).

In most cases, the islet preparation is infused into the portal vein or one of its major branches. The authors' technique is to use a 5-French micropuncture kit to place a catheter into the anterior portal vein or splenic vein. Anticoagulation of the patient is necessary as the islet preparation includes injured tissue that will induce a hypercoagulable state [27] and 70 units of heparin per kg body weight administered intravenously is typically utilized. Portal pressures are measured at the beginning and throughout infusion of islets, with infusion held if pressures increase by greater than 25 cm H_2O. Portal pressure increase is expected, as the islet preparation volume is embolizing within the portal venous system, which has a limited capacity for tissue [28] of about 0.25 mL of tissue per kg body weight. In the situation where portal pressures remain elevated during infusion, islets can be safely placed within an omental pouch or other extraportal site [29].

Laparoscopic-assisted, laparoscopic, and robotic total pancreatectomy with islet autotransplant have been described [30–32]. In a case-control series of laparoscopic-assisted total pancreatectomy compared to an open procedure in children (21 patients in each group), perioperative morbidity, operative time, length of stay and outcomes were similar between laparoscopic and open groups, with a higher use of opioids at 2 years post-procedure in the laparoscopic group [30]. Other case series demonstrate the feasibility of both laparoscopic and robotic approaches to TPIAT [31,32]. One issue continues to be the inflammation and scarring associated with CP and the potential effect of this state on the ability to safely perform the dissection via laparoscopy or robotically.

Postoperative Care

Many of the postoperative complications associated with total pancreatectomy and islet autotransplant are common with other similar procedures such as a Whipple procedure. These include anastamotic leak from GI tract or bile duct, postoperative abscess, and postoperative bleeding. Other complications are related to and unique to the islet autotransplant portion of the procedure. Postoperative management of these patients includes close monitoring for these complications and care supportive of the unique features of this operation. In a large, multicenter prospective study of patients after TPIAT [6], complications included need for reoperation for bleeding, portal vein thrombosis, intra-abdominal abscess, and wound infection (Table 66.3).

A common feature in this operation is delayed gastric emptying. In this population of patients this seems to be present for 3–6 weeks after surgery. There is some evidence that laparoscopic or robotic procedures may reduce the duration of this problem, but this has not yet undergone careful study. Current protocol in our institution is to place a gastrojejunostomy tube at the time of surgery, with initiation of tube feedings the morning

Table 66.3 Postoperative complications in a multicenter study of 279 patients after total pancreatectomy with islet autotransplantation [6].

	Incidence: Adults	Incidence: Pediatrics
Complication	***n*** **= 195**	***n*** **= 83**
Reoperation within 30 days	11%	7%
Abdominal infection requiring drainage	9%	3%
Bile duct obstruction/leak	2%	2%
Portal venous thrombosis	10%	2%
Mechanical ventilation >24 hours postoperative	3%	1%
Vasopressor use >24 hours postoperative	3%	6%
Pulmonary embolus/deep venous thrombosis	4%	0%

after surgery. The patient can be transitioned to oral intake and the gastrojejunostomy tube can be removed several weeks postop. Pancreatic exocrine insufficiency is common in patients with CP in the preoperative state, with nearly 50% of patients on pancreatic enzyme supplementation. Of course, after removal of the pancreas all patients have a lifelong requirement for pancreatic enzyme supplementation. During tube feeds, this deficiency is addressed using an immobilized lipase cartridge in line with the tube feeds (Relizorb R). Pancreatic enzymes are initiated as the patient transitions to oral intake and adjusted as necessary.

Anticoagulation is important in the operating room and postoperatively due to infusion of the hypercoagulable islet tissue. Various regimens include low-dose heparin infusions or moderate doses of low-molecular weight heparin. Patients should be imaged 4–6 days postoperatively for presence of portal vein thrombosis and if this condition is identified, patients should be fully anticoagulated for 3 months postoperatively [33].

Pancreatic islets are routinely cultured for presence of bacterial contamination prior to infusion. If these cultures return positive (this occurs in 40–60% of cases), appropriate tailored antibiotic therapy is initiated and continued for 7 days to treat the positive cultures. In one series of more than 250 patients, this approach resulted in no concordant bacterial infections [34].

Pain management after TPIAT is a vexing problem. Essentially every patient is habituated to narcotics, and appropriate control of pain without oversedation is challenging. An epidural catheter is contraindicated, due to the need for intraoperative anticoagulation. Typical therapy includes a multimodal management approach that can include i.v. narcotics, adjuncts such as ketamine or dexmetatomidine, and local therapies including paravertebral catheters or long-acting abdominal wall blocks. A key component of this management is in counselling of the patient and their support persons on the difficulty of achieving adequate pain control for the first several days following surgery. As the patient recovers from surgery, transition to long-acting narcotics to treat both the narcotic dependency and postop pain is appropriate, with weaning of narcotics over the months following surgery.

Glycemic Management

The important concept to preserve islet function after autotransplantation is maintainance of normoglycemia. Hyperglycemia can lead to both poor engraftment of cells in the perioperative period, and loss of islet cells after TPIAT [35,36]. Management of blood glucose to promote optimal islet function begins in the operating room. Solutions containing dextrose should be minimized in the intraoperative period as this has been shown to be associated with sustained intraoperative and postoperative hyperglycemia. Insulin should be administered to maintain blood glucose levels between 80 and 120 mg/dL and postoperatively an insulin infusion should be maintained to keep blood glucose within this range. Patients are typically transitioned to long-acting insulin preparations as enteral nutritional requirements are met. Most patients are maintained on insulin for the first 3 months after islet autotransplant with gradual weaning of insulin as tolerated.

Outcomes after Total Pancreatectomy and Islet Autotransplantation

The major outcome of interest in patients receiving TPIAT is relief of pain, with other outcomes including need for insulin and quality of life. Studies from multiple centers have recently been evaluated in a meta-analysis from the Dutch Pancreatitis Study Group [37] where outcomes from 14 studies that included 1255 patients were evaluated. In this meta-analysis, at 1 year after total pancreatectomy with islet cell autotransplantation, opioid-free rate had improved from between 0% and 15% to 63% (95% CI: 46–77), and the insulin-free rate had decreased from between 89.5% and 100% to 30% (95% CI: 20–43). Alcohol as the cause of pancreatitis was associated with lower insulin-free rate. Quality of life significantly improved after TPIAT.

In one of the largest single center studies published to date, Chinnakotla and coauthors reported long-term outcomes in adults ($n = 490$) and children ($n = 91$) after TPIAT [38]. They reported 10-year survival of 90%, with 1 year narcotic-free rates of 67% and insulin-free rates of 18% (adults) and 31% (children) (Fig. 66.2). Pediatric patients had significantly improved outcomes compared to adults. Other larger series have shown comparable results [39,40] An ongoing prospective multicenter trial is actively enrolling patients from nearly a dozen institutions to evaluate postoperative outcomes and relationship to preoperative findings [6,41].

There have been two long-term studies examining the durability of TPIAT for resolution of pain, glycemic control, and quality of life. In a 5-year follow-up study, Wilson and coauthors report their results in 195 patients [40]. Annual visits and hospitalizations decreased from 6 and 4, respectively, to 0 for each of years 1, 2, and 5 after surgery. Postoperative quality of life scores significantly improved with a durable improvement at 5 years for both physical and mental well-being. Finally, median oral morphine equivalents were significantly reduced and remained significantly lower than preop (214 mg/kg before surgery, 69 mg/kg at 5 years postoperatively). A second study, reporting 10-year

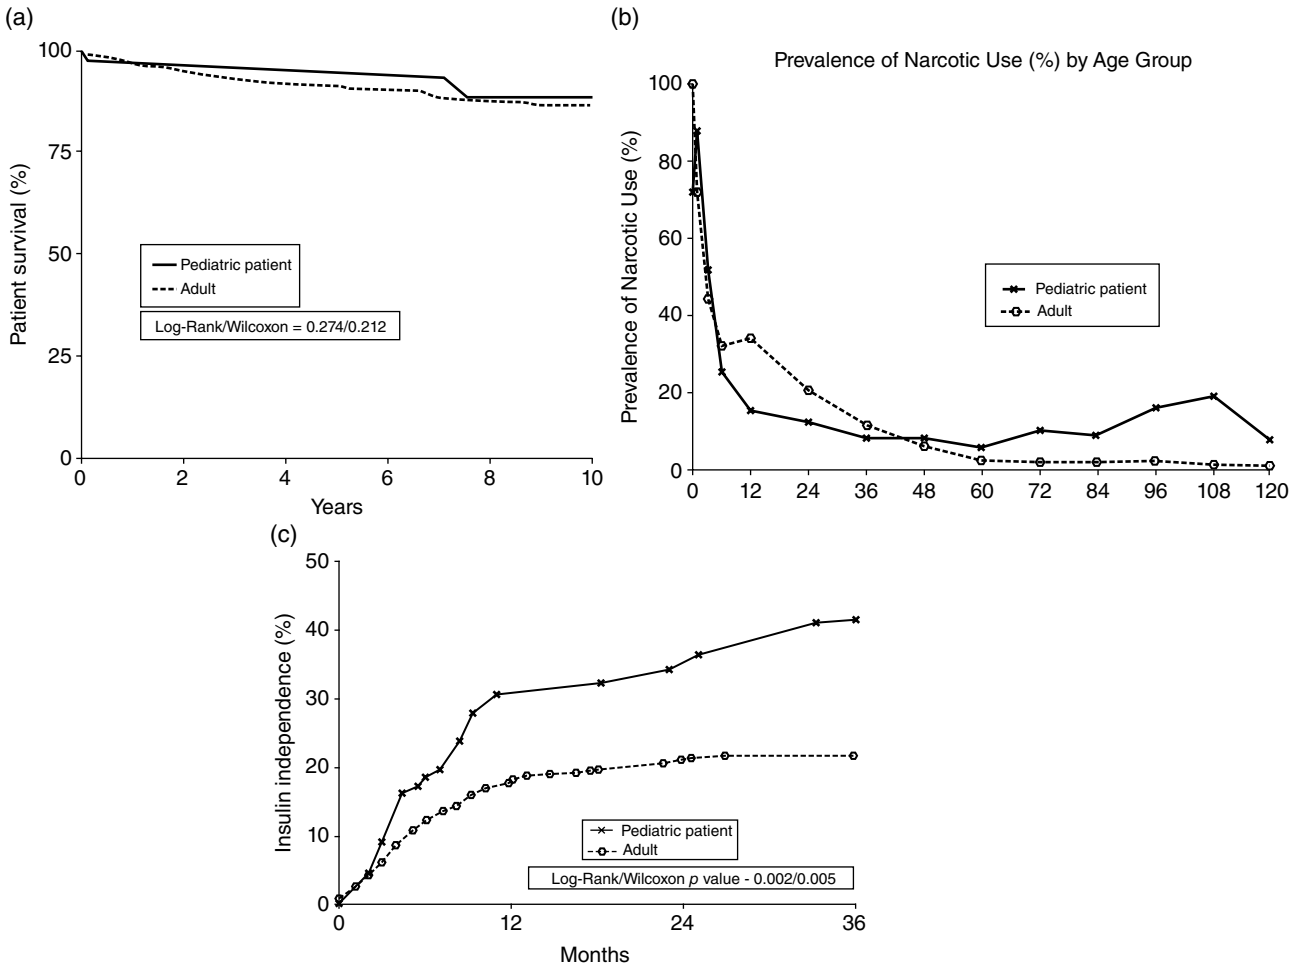

Figure 66.2 Outcomes after total pancreatectomy with islet autotransplant (TPIAT) in 581 patients at a single center [38]. (a) Ten-year actuarial survival in adults and children after TPIAT. (b) Narcotic-free percent in adults and children after TPIAT. (c) Insulin-independence in adults and children after TPIAT. *Source:* Chinnakotla et al. 2015 [38]. Reproduced with permission.

outcomes in 215 patients [42], noted a 10-year actuarial survival rate of 72%. Narcotic use declined with time: the rates were 50% at 5 years and 37% at 10 years. At 10 years, the rate of insulin independence was 20%; the rate of partial graft function, 32%. Transplantation of islet equivalents/kg >4000 was the strongest predictor of islet graft function at 10 years. Health-related quality of life continued to improve at 10 years, even in patients on narcotics.

In conclusion, total pancreatectomy with islet autotransplantation has become a viable option for selected patients with painful chronic pancreatitis, with long-term success in terms of pain relief and glycemic control.

Minimally Invasive Surgical Management of Chronic Pancreatitis

Gilbert Z. Murimwa, Herbert J. Zeh III, and Matthew R. Porembka

Department of Surgery, University of Texas Southwestern Medical Center, Dallas, TX, USA

Introduction

The introduction of laparoscopy, and more recently robotics, into abdominal surgical practice has revolutionized the approach to complex surgical conditions. The first laparoscopic procedure for chronic pancreatitis (CP) was reported in 1994 by Gagner and Pomp who successfully performed a pylorus-preserving pancreaticoduodenectomy (PD) on a 30-year-old woman [1]. In 1996, Cuschieri et al. described a series of five laparoscopic distal pancreatectomies (LDP) with splenectomy in patients with CP, with good perioperative outcomes [2]. Due to concerns of excessive morbidity, the expansion of laparoscopic, and robotic pancreatic surgery was initially met with resistance. Over the past two decades, however, minimally invasive approaches have slowly been integrated into the repertoire of high-volume centers, with rates of mortality and morbidity equivalent to those of open procedures [3]. In addition, with the advent of robotic assistance, surgeons can now benefit from binocular three-dimensional vision, scaling, stabilization of tremor, reduced operator fatigue, and improved ergonomics from the console–surgeon interface. As the technology continues to evolve, and surgeons progress through their learning curve, minimally invasive approaches and indications for pancreatic pathology are continuing to expand.

Traditionally, the majority of surgical interventions for CP are performed through an open approach. The literature continues to grow supporting the safety and comparable efficacy of minimally invasive versus open pancreas surgery; however, most data combines both benign and malignant indications as well as laparoscopic and robotic interventions. As only a few studies have focused solely on benign indications, it may be reasonable to infer that outcomes of larger laparoscopic and/or robotic series can be used to provide insight into the applicability of minimally invasive approaches to CP. This chapter, therefore, will summarize the current data on the safety, feasibility, and efficacy of minimally invasive procedures for CP, but also draw on the broader available literature on minimally invasive pancreatic surgery performed for other indications.

Generally, surgical strategies for CP can be categorized into resection-type procedures, drainage-type procedures, and combination-type procedures involving resection and drainage (Table 67.1). In addition, minimally invasive surgery can be broadly defined as laparoscopic or robotic assisted.

Patient Selection

Laparoscopic and robotic pancreatic resection, drainage, or combination procedures offer the advantages of minimally invasive surgery to appropriately selected patients. Initially it was believed that patient factors such as age, comorbidities, body habitus, and prior operations were useful in selecting which patients should be candidates for minimally invasive operations. Recently the Miami Consensus Guidelines sought to provide evidence-based recommendations on the role and appropriate use of minimally invasive pancreatic resection [4].

Within the consensus guidelines, neither patient factors nor operative plan were found to impact patient outcomes and thus should not be used to guide patient selection for laparoscopic or robotic interventions. In general, robotic PD (RPD), with or without vascular resection, should only be performed in high-volume centers with experienced surgeons; however, the need for vascular resection itself should not preclude patients from minimally invasive options [5]. Moreover, the Miami Consensus states that patients should not be

excluded from RPD based on obesity, patient age, or previous abdominal surgery [6].

Girgis et al. actually found a decrease in operative time, estimated blood loss, and POPF rate when compared to open PD for obese patients undergoing robotic pancreatic resection [6]. In an updated series of the University of Pittsburgh's first 500 cases of RPD, expanding patient selection criteria to include higher Charlson comorbidity scores, patients who received neoadjuvant therapy for PDAC, and vascular resections did not impact operative time, conversion rates, blood loss, or clinically relevant POPF [7]. Additionally, Kim et al. investigated whether anatomic variation of the right hepatic artery led to differences in pre- and postoperative outcomes and finding no difference, concluding that these variations should not be considered contraindications to the robotic approach [8]. In the hands of appropriately trained surgeons who are through their learning curve, robotic and other minimally invasive pancreatic surgery is comparable in efficacy to open approaches with the added benefits of improved postoperative recovery associated with MIS.

When managing CP, the specific procedure performed will continue to remain dependent on anatomic considerations such as the presence of a mass in the head of the pancreas, peripancreatic fluid collections, and pancreatic ductal involvement. A flow diagram for decision-making is depicted in Fig. 67.1. Importantly, given the infrequent indication for surgical interventions in CP, minimally invasive pancreatic operations for CP are best delivered at high-volume tertiary centers, by experienced pancreatic surgeons, in the context of multidisciplinary assessment. The operative approach to such patients (open, laparoscopic, or robotic assisted) must be dictated by surgeon experience and comfort level.

Resection Procedures

Total Pancreatectomy with Islet Autotransplantation

Total pancreatectomy with islet autotransplantation (TPIAT) is a rare procedure that is performed in only a

few specialized centers across the United States, with mortality and morbidity up to 16% and 70%, respectively [10]. As expected, the majority of such procedures are completed through an open approach, with laparoscopic or robotic-assisted approaches infrequently reported (Fig. 67.2). A single-center retrospective review of six patients with CP who underwent fully robotic-assisted TPIAT reported a mean operative time of 712 minutes and mean estimated blood loss (EBL) of 630 mL and no mortality [11]. At 1 month follow-up, all five patients who initially presented with intractable chronic pain syndrome were in the process of weaning off narcotics.

As early as 2009, cases of robotic-assisted laparoscopic distal pancreatectomy with autologous islet transplantation for CP were being reported [12]. The largest reported case series of robotic-assisted laparoscopic total pancreatectomy includes 10 patients with both benign and malignant pathology [10]. One of three patients with CP underwent AIT; seven patients had concomitant splenectomy while two were spleen-preserving. Median operative time was 560 minutes and median EBL was 650 mL. There was no 90-day mortality, and two Clavien–Dingo grade III complications were reported in two patients, including pleural effusion and fascial dehiscence. The median length of stay (LOS) was 10 days. These results are comparable to a more recent series of 12 TPIAT perfomed through an open approach [13].

Pancreaticoduodenectomy (Whipple)

The last two decades have witnessed an increasing number of single-institution reports of minimally invasive PD, but the efficacy of either laparoscopic or robotic PD for CP still requires larger series and a more robust assessment of outcomes. It can be inferred from studies that include benign and malignant indications that the minimally invasive PD is a safe and feasible procedure for patients treated at high-volume centers. A recent systematic review, for example, comparing laparoscopic and open PD (17.5% for benign disease) found similar rates of postoperative morbidity [15]. The study included 25 articles encompassing 746 cases of laparoscopic PD: 386 (52%) were pure laparoscopy, 121 (16%) with laparoscopic assistance, 231 (31%) with robotic assistance, and

5 (1%) with hand assistance. Overall, open conversion was necessary in 9.1% of all cases. Mean operative time was 464 minutes and EBL 321 mL. The morbidity rate was 41%, including 22% patients developing pancreatic fistula, and mortality 1.9%. Mean LOS was 13.6 days. Pure laparoscopy was associated with shorter operative times, less blood loss, and lower rates of pancreatic fistula. Laparoscopic assistance had shorter operative times than robotic assistance, but higher rates of blood loss and pancreatic fistulas. The largest available single-institution review of robotic PD (500 cases) performed for various indications reported outcomes comparable to open historic controls with only a 6% rate of conversion in the most recent 100 cases despite broad indications and expanded patient selection [7]. As institutions and individual surgeons progress futher past their learning curves, outcomes appear to remain consistent despite increasing complexity of operations performed.

Distal Pancreatectomy (DP)

Similar to pancreatic head resections, the majority of studies comparing laparoscopic with open distal pancreatectomy do not stratify between benign and malignant indications. Specifically, data on minimally invasive distal pancreatectomy for CP are lacking and limited to a handful of small series such as that by Fernandez-Cruz et al., who reported a series of five CP patients who underwent LDP with spleen preservation, compared to 41 open pancreaticoduodenectomies with or without splenectomy [17]. This early study suggested that LDP for CP was feasible with acceptable outcomes.

LDP appears to be a safe and feasible approach for the treatment of left-sided pancreatic pathology. A systematic review of 18 studies by Venkat et al. (1814 patients) comparing laparoscopic (43%) and open (57%) distal pancreatectomies for all indications found that the laparoscopic technique was associated with decreased intraoperative blood loss by 355 mL, surgical site infections (3% vs. 8%), postoperative complications (34% vs. 44%), and decreased length of hospital stay by 4 days [18], with no differences in operative time, postoperative pancreatic fistula, or mortality. In addition, two single-institution retrospective series also suggest the robotic approach to distal pancreatectomy may have lower rates of open conversion, and higher rates of splenic preservation compared to conventional laparoscopy [31,32]; this latter benefit, however, may not be translatable in the setting of adhesive CP. In a Dutch series of 401 consecutive minimally invasive DP, 25% were performed robotically, and similar to the effect seen in RPD, outcomes remained consistent as surgeons progressed further beyond their learning curve despite expansion of indications and relaxed patient selection [16]. Splenic preservation, performed in 27% of patients, also reduced operative time and eliminated conversion to open in this study, which notably did not include any patients with CP [16]. Contemporary series of high-volume surgeons performing this operation in the setting of CP are thus needed to better characterize outcomes in this patient population.

Drainage Procedures

Lateral Pancreaticojejunostomy (Puestow)

The conventional open lateral pancreaticojejunostomy (LPJ) can be associated with high morbidity rates of up to 25% and mortality <5% [20]. Limited case reports of laparoscopic LPJ have shown it to be feasible, safe, and effective [20,22]. In 2014, Khaled et al. described five laparoscopic LPJ for CP with a median operative time of 278 minutes and EBL of 150 mL with no mortality and 5-day LOS. At a follow-up of 14 months, four out of the five patients were pain-free [22]. These results are comparable to a recent literature review of 37 laparoscopic LPJ that reports a mean operative time of 218 minutes, 0% mortality, and mean 5.5 day LOS. There was a 13.5% rate of open conversion and 13.5% complication rate. Importantly, at variable rates of follow-up between 5 and 84 months, 89% of patients were pain-free [20].

The first case report of a robotic-assisted LPJ in a 14-year-old child with idiopathic CP was reported in 2011. Operative time and LOS were 390 minutes and 8 days, respectively, with the patient remaining asymptomatic and pain-free at 2 years postoperatively [21]. Subsequently two new cases with satisfactory outcomes have been reported including a video demonstrating one group's approach to robotic-assisted LPJ [33,34]. These cases highlight the potential for high-volume centers to safely expand minimally invasive, and particularly robotic approaches to traditionally open interventions for CP as surgeon comfort with minimally invasive techniques increases.

Cyst Gastrostomy

Complications of pancreatitis such as pseudocyst, walled-off necrosis (WON), and infected WON are increasingly being managed by minimally invasive techniques. Although WON historically has been treated with open cyst gastrostomy (or cyst jejunostomy if the WON is not retrogastric in location) and necrosectomy, the associated operative morbidity of this approach has spawned the application of endoscopic and minimally invasive surgical alternatives (Fig. 67.3) [24,26].

Deciding between an endoscopic versus minimally invasive approach to cyst gastrostomy and necrosectomy should take several factors into consideration. Endoscopic

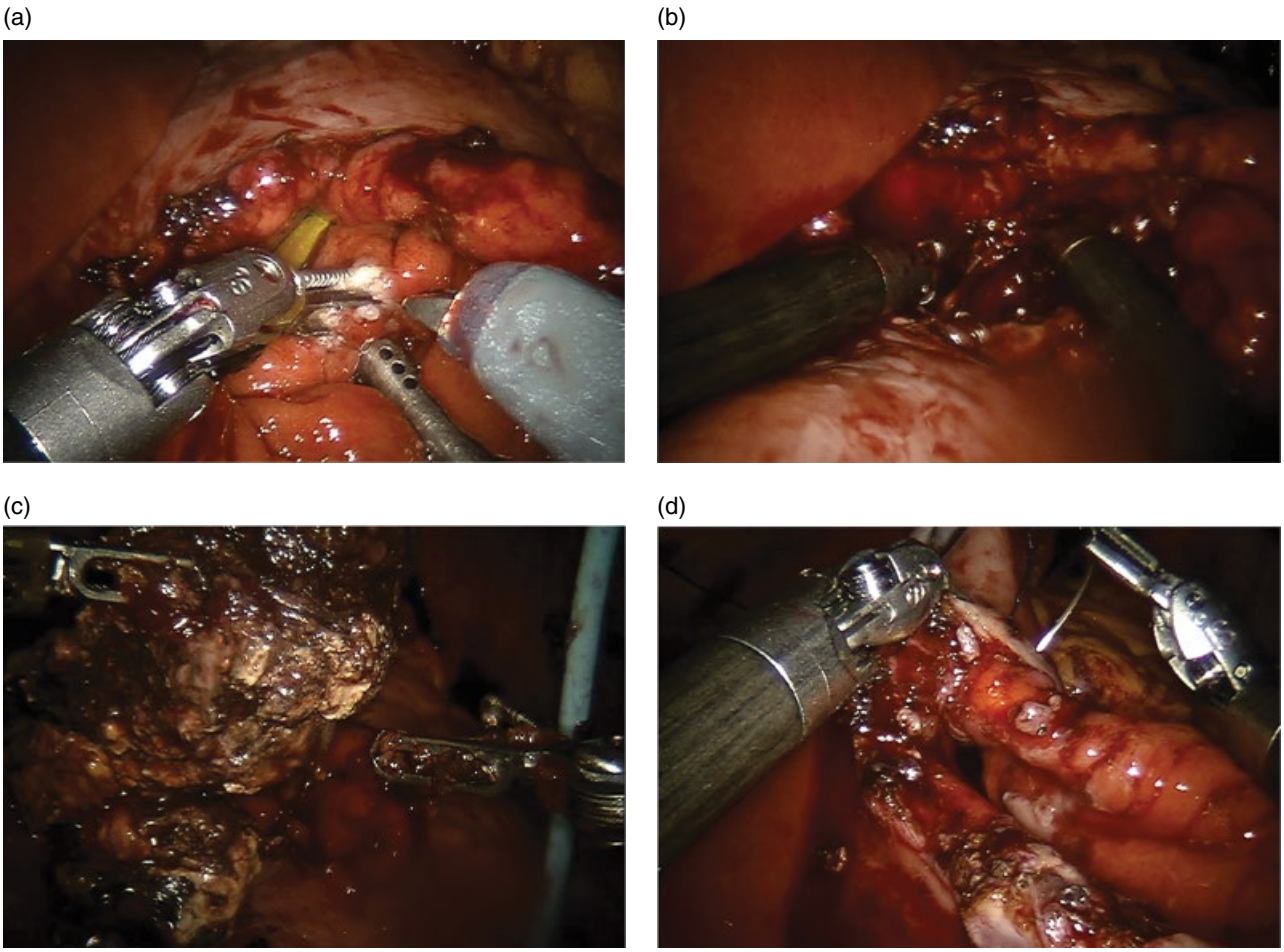

Figure 67.3 Robotic-assisted laparoscopic cyst gastrostomy. (a) Anterior cyst gastrostomy. (b) Posterior cyst gastrostomy. (c) Pancreatic debridement. (d) Gastrostomy closure.

and laparoscopic cyst gastrostomy have been shown to have comparable mortality and morbidity, but the reintervention rate is usually higher using the endoscopic route [26]. Khreiss et al. compared 20 patients with sterile WON undergoing minimally invasive surgical drainage with 20 patients undergoing endoscopic drainage. In the laparoscopic group, the median operating room time was 167 minutes with 30 mL EBL. There were no open conversions, reoperations, or periprocedural mortality, and both groups had equal complication rates (20%). Forty-five percent of the endoscopic patients, however, required reintervention for residual WON, compared to 15% in the minimally invasive surgical group. Despite a shorter LOS in the endoscopic group (2 days vs. 7 days), surgical patients had a faster time to resolution (mean 0.42 months vs. 3.6 months). The authors concluded that minimally invasive cystgastrostomy and debridement for WON can be advantageous, especially if a concomitant cholecystectomy is needed at the time of the WON drainage. A similar retrospective review of 21 patients with pancreatic necrosis (14/21 with sterile necrosis) by Worhunsky et al. reported that 19 of 21 patients (90%) were successfully debrided in a single operation without requiring additional interventions [25]. Recently, robotic cyst jejunostomy with RNY reconstruction has been reported for resolution of two simultaneous, complex WON with operative time of 180 minutes, EBL of 25 mL, and 7-day LOS [23]. Again, although reports are still rare, high-volume surgeons at centers routinely performing minimally invasive pancreatic surgery are able to safely translate these new approaches to classic operations for the management of CP.

Video-Assisted Laparoscopic Retroperitoneal Debridement

Video-assisted retroperitoneal debridement (VARD) is a minimally invasive technique that allows debridement of WON via a retroperitoneal route. The presence of a retroperitoneal drain—especially on the left side—is a

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

requirement for a VARD procedure, since it provides a direct unimpeded route to the necrosum, thereby avoiding associated peritoneal inflammation and adhesions. Briefly, the procedure entails placing a laparoscopic port into the retroperitoneal cavity with the guidance of a percutaneous drain. Irrigation, suction, and direct debridement are gently conducted under direct visualization. A large sump drain is left in the cavity at the conclusion of the operation. Postoperatively, scheduled lavage using normal saline or dilute hydrogen peroxide is repeated until the effluent is clear.

Horvath et al. analyzed 40 patients with pancreatic necrosis across six tertiary care centers; 9 of whom were treated with drains alone, 25 with VARD, and 6 with planned open surgery [27]. Patients already treated with a percutaneous drain were enrolled, and received an additional retroperitoneal drain (within 48 hours of enrollment) that was upsized every 3–4 days until a 20-F catheter was reached. Patients underwent a computed tomography (CT) scan on postdrain day 10–14; those exhibiting >75% reductions in collection size were treated with drains alone. Out of 25 patients requiring VARD, 10 (40%) required an open conversion and 19% required a second VARD. The most common cause of open conversion was a centromedial collection with extension into the mesenteric root that was not accessible from the flank. The mean operative time was 135 minutes. There were four (16%) primary VARD-related complications including bleeding and enteric fistula, and nine secondary complications (pneumonia, deep vein thrombosis, respiratory failure, bacteremia, pseudocyst, pancreatic fistula). The median LOS was 64 days, and there were no 30-day mortalities, though there was one death (4%) between 3–6 months following discharge.

Overall, low reported rates of morbidity and mortality for VARD compare favorably to open necrosectomy. As 23% of 40 patients in the Horvath study were successfully treated with percutaneous drainage alone, and in accordance with the "step-up approach," it is reasonable to begin with percutaneous or endoscopic drainage [27,32]. Of note, 75% size reduction of the necrotic collection at 10–14 days on CT scan in the Horvath study predicted success of percutaneous drains alone with 100% accuracy [27]. If patients fail to progress clinically, treatment may be escalated to additional drains, or a VARD.

Combination Procedures (Resection and Drainage)

Frey Procedure

The surgical tenets of the minimally invasive Frey procedure are closely modeled after the open technique, as depicted in Fig. 67.4. Data from Europe and the United

States on outcomes following laparoscopic Frey procedure for CP are limited and exclusively comprise case reports [29].

A single-institution experience in China described 9 laparoscopic and 37 open Frey procedures for CP [30]. In two (22%) laparoscopic cases, open conversion was necessary due to inability to locate the pancreatic duct. In the seven laparoscopic completions, mean operating room time was 323 minutes with 57 mL of blood loss. There was one postoperative complication of post-pancreatectomy hemorrhage, with no mortality. Average LOS was 7 days. At 3-month follow-up, all seven patients had significantly decreased visual analog scale (VAS) scores for pain. Outcomes were comparable to the open cohort. The authors recommended a minimum pancreatic duct width of >8 mm for successful laparoscopic intervention.

Beger Procedure

Available data on the minimally invasive Beger procedure is scarce. A case report of a laparoscopic Beger procedure with "Berne modification" in a patient with an inflammatory head mass causing an intrapancreatic common bile duct stricture documented an operative time of 285 minutes [22]. The patient was discharged after 5 days without complications and at 16-month follow-up reported mild pain, controlled with one-third of the preoperative oral opioid dose.

Conclusion

Although the data for minimally invasive approaches for chronic pancreatitis continues to be limited to small retrospective studies and case reports, there is sufficient evidence from mixed indication studies to demonstrate that laparoscopic and robotic interventions for the pancreas are safe and feasible in highly specialized centers. Analogous to the open approach, a myriad of resection-, drainage-, and combination-type procedures can be performed for CP and surgeon comfort and expertise rather than patient factors should determine the appropriate role for minimally invasive approaches. Nevertheless, further comparative studies on the efficacy of these approaches and their impact on quality of life for patients with CP are needed. The data for malignant indications as it currently stands is promising and points to increasing uptake of the robotic approach.

Epidemiology of Autoimmune Pancreatitis

Terumi Kamisawa

Department of Internal Medicine, Tokyo Metropolitan Komagome Hospital, Tokyo, Japan

Introduction

There are two histologic types of autoimmune pancreatitis (AIP): (i) lymphoplasmacytic sclerosing pancreatitis (LPSP), which is called type 1 AIP; and (ii) idiopathic duct-centric pancreatitis (IDCP), which is called type 2. Type 1 AIP is recognized as a pancreatic manifestation of IgG4-related disease [1,2].

Since 2002, several diagnostic criteria for AIP have been identified worldwide, and international consensus diagnostic criteria (ICDC) have been developed to incorporate the diagnostic strategies used in the different criteria [3].

Four nationwide epidemiologic surveys of AIP have been conducted in Japan [4–7], as well as three international multicenter surveys [8–10]. In this chapter, the epidemiology of AIP is described based on the findings of these surveys.

Nationwide Surveys of Autoimmune Pancreatitis in Japan

The first nationwide survey in Japan analyzed patients who visited selected hospitals during 2002 [4], the second survey was conducted in 2007 [5], and the third survey was conducted in 2011 [6]. The estimated total number of AIP patients was 1700 in 2002, 2790 in 2007, and 5745 in 2011. The rapid increase in the number of AIP patients might be explained by increased recognition of the AIP concept and development of diagnostic criteria in Japan.

The fourth nationwide survey was conducted in 2016 according to the Japanese diagnostic criteria 2011 [11]. The estimated number of AIP patients was 13,436, with an overall prevalence rate of 10.1 per 100,000 population. The number of newly diagnosed AIP patients was estimated to be 3984, with an annual incidence rate of 3.1 per 100,000 population. The male to female ratio was 2.94, and the patients' mean age was 68.1 years. At diagnosis, 63% patients were asymptomatic and nearly half presented with jaundice. Among the 1449 patients, 84.5% presented with high serum IgG4 levels (≥135 mg/dL), and serum IgG4 levels were significantly higher in patients who developed extrapancreatic lesions (612.2 ± 577.0 mg/dL) than in those who did not (406.4 ± 405.4 mg/dL) ($P < 0.01$). Nearly 50% of patients showed localized enlargement of the pancreas. Pancreatic cysts were found in 9% and calcifications in 6%. Pancreatic tissues were obtained in 64%, and tissue samples were obtained mainly by endoscopic ultrasound-guided fine-needle aspiration. Extrapancreatic lesions were detected in 873/1456 (60%) patients as follows: 357 intrapancreatic sclerosing cholangitis, 291 sialadenitis/dacryoadenitis, 149 retroperitoneal fibrosis, 113 hilar sclerosing cholangitis, and others. Steroid treatment was given to 84%, and it was effective in 98.6%. The most common daily prednisolone dose was 30 mg (64%). Maintenance steroid treatment was given in 85% and the relapse rate was 23.4%. The mortality rate was favorable, but malignant tumors were detected in 242 (16%) patients including 18 patients with pancreatic cancer. Pancreatic cancer accounted for death in one-quarter of fetal cases.

First International Survey of Autoimmune Pancreatitis

The first international multicenter survey of AIP was carried out in 2009 and involved 10 centers in 5 Asian countries (Japan, Korea, Taiwan, China, and India) [8].

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.
© 2023 John Wiley & Sons Ltd. Published 2023 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/beger/thepancreas4e

A total of 327 AIP patients (258 males, 69 females; average age 60.0 years) diagnosed according to the Asian diagnostic criteria [12] were enrolled.

The most common initial symptom was obstructive jaundice, followed by weight loss and abdominal pain. Diffuse swelling of the pancreas was frequent in Japan (64%) and Korea (81%), but segmental swelling of the pancreas was more frequent in Taiwan (70%) and China (72%) ($P < 0.01$). Increased serum IgG4 levels were seen in 58–100% of patients in Japan, Korea, and Taiwan. Pathologically, almost all AIP patients in Asia were diagnosed as LPSP. Steroid therapy was the major and effective therapeutic strategy, but the rate of resection or bypass operation was higher in Taiwan and China ($P < 0.01$).

Japan, Korea, Taiwan, and China are geographically adjacent, and their populations appear to share a common genetic background. The features of AIP patients were fundamentally similar and most of them were type 1 AIP in these countries. Differences in the clinical and pathophysiologic characteristics of AIP in these areas might be due to differences in the rates of recognition of this disease.

Second International Survey of Autoimmune Pancreatitis

The second international multicenter survey of AIP in 2010 involved 15 institutes in 8 countries (Japan, Korea, Taiwan, India, the United States, Germany, Italy, and the United Kingdom) [9]. A total of 731 AIP patients were enrolled, with 204 cases confirmed histologically as LPSP and 64 cases confirmed as IDCP. The AIP patients were diagnosed according to various diagnostic criteria.

LPSP patients were approximately 16 years older than IDCP patients (61.6 years vs. 44.8 years). No sex difference was observed between the two groups. Obstructive jaundice was a more frequent presentation in LPSP than in IDCP (75% vs. 47%, $P < 0.01$), whereas abdominal pain (41% vs. 68%, $P < 0.01$) and acute pancreatitis (5% vs. 34%, $P < 0.01$) were more frequent presentations in IDCP patients. Compared to IDCP patients, LPSP patients were more likely to have diffuse pancreatic swellings (40% vs. 25%, $P < 0.05$), increased serum IgG4 levels (63% vs. 23%, $P < 0.01$), retroperitoneal fibrosis (7% vs. 0%, $P < 0.05$), and salivary gland swelling (12% vs. 0%, $P < 0.01$), but they were less likely to have ulcerative colitis (1% vs. 16%, $P < 0.01$). IDCP patients more frequently underwent surgery (60% vs. 78%, $P = 0.01$). Good therapeutic responses to steroid treatment were seen in both groups, but IDCP patients had a significantly lower relapse rate (36% vs. 5%, $P < 0.01$).

In nonhistologically confirmed AIP patients, the most common initial symptom was obstructive jaundice in six countries, but it was less frequent in Italy (44%) and Germany (13%). Abdominal pain was the most frequent initial symptom in India (86%) and Germany (63%). Acute pancreatitis was seen frequently in Germany (66%) and Italy (32%). Increased serum IgG4 levels were detected in 85–100% of AIP patients in Japan, Taiwan, India, and the United States, but only in 50–61% in other countries. Italian AIP patients frequently had ulcerative colitis (30%). Steroids were given in 69–100% of AIP patients. The initial prednisolone dose was 1 mg/kg/day in three countries, 0.6 mg/kg/day in two countries, and 30–40 mg/day in the remaining three countries. This dose was tapered by 5 mg every 1–2 weeks. The time from initiation to cessation of steroid therapy ranged from 3 months to 2 years. All patients showed good responses to steroid treatment. The relapse rate in steroid-treated patients ranged from 15% to 64% (Table 68.1).

The clinical profiles of patients in six countries were similar to those of LPSP patients. However, Italian and German AIP patients had different clinical profiles, which appeared to include a mixture of LPSP and IDCP.

Third International Survey of Autoimmune Pancreatitis

The third international multicenter survey of AIP in 2012 involved 23 institutes in 10 countries (Japan, Korea, Taiwan, the United States, Germany, Italy, the United Kingdom, Hungary, Sweden, and France) [10]. The patients were diagnosed using the ICDC [3], and the survey focused on long-term outcomes, including organ involvement, treatments, relapse frequency, and long-term sequelae.

A total of 1064 patients who met the ICDC [3] for type 1 ($n = 978$) or type 2 ($n = 86$) were included. Average ages of type 1 and type 2 patients were 61.4 and 39.9 years, respectively. The proportion of males was 77% among type 1 patients and 55% among type 2 patients ($P < 0.01$). The proportion of patients diagnosed with type 2 AIP was lower in Asian countries (3.7%) than in both Europe (12.9%, $P < 0.01$) and North America (13.7%, $P < 0.01$) (Fig. 68.1).

In type 1 patients, jaundice was the most common indication (63%), followed by abdominal pain, but in type 2 AIP, it was abdominal pain and inflammatory bowel disease. The majority (74%) of type 1 patients were treated initially with steroids, while only 62% of type 2 patients were treated with steroids ($P = 0.01$).

NA: not available; OOI: other organ involvement.

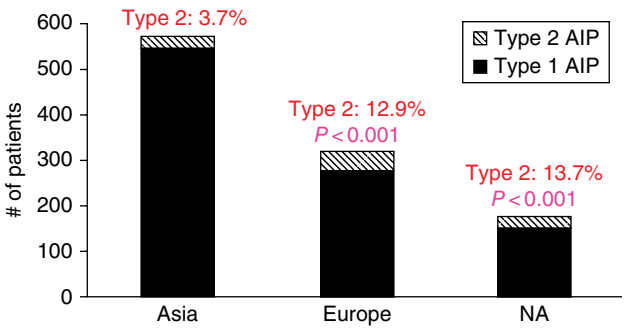

Figure 68.1 Regional distribution of type 1 and 2 AIP based on the country of diagnosis. *Source:* [10] / BMJ Publishing / CC BY.

Almost all patients with type 1 and 2 AIP achieved remission. A total of 302 (31%) type 1 patients experienced at least one disease relapse, compared to 8 (9%, $P < 0.01$) of type 2 patients. Most relapses occurred in the biliary system or pancreas for type 1 patients, while relapses in type 2 patients were limited to the pancreas. Several relapses occurred in type 1 AIP, but only one in type 2 AIP (Table 68.2). Steroid retreatment remained effective for inducing remission with or without alternative treatment, such as azathioprine.

Conclusions

With increased recognition of the AIP concept and development of diagnostic criteria, the number of AIP patients has rapidly increased in Japan. The estimated number of AIP patients in the recent nationwide survey in Japan was 13,436, with an overall prevalence rate of 10.1 per 100,000 population.

International surveys of AIP showed the regional and ethnic differences in the pathologic and clinical features of AIP as well as the quite different profiles of type 1 and type 2 AIP patients. To improve our understanding of this disease, further multinational collaborations are required.

Molecular Immunology and Pathogenesis of Autoimmune Pancreatitis

Yoh Zen

Institute of Liver Studies, King's College Hospital, King's College London, London, UK

Introduction

Similar to many other immune-mediated conditions, a likely pathogenetic mechanism for autoimmune pancreatitis (AIP) is the exposure of genetically susceptible individuals to environmental or intrinsic factors that results in orchestral immune reactions. Among the two distinct subtypes of AIP, type 1 has been the main target of pathogenetic studies [1]. Therefore, this chapter focuses on the prototypic type of AIP. Although the molecular features of type 2 AIP are currently unclear, recently obtained findings on the less common form of AIP are also briefly introduced in the last section.

Type 1 Autoimmune Pancreatitis

Genetic Predisposition

The strongest genetic risk is related to human leukocyte antigens (HLA), with the subtypes DRB1*0405 and DQB1*0401 known to increase the susceptibility of Japanese populations to type 1 AIP [2]. The absence of aspartic acid at HLA DQβ1 57 has also been correlated with disease relapse in Koreans [3]. A genome-wide association study of 835 Japanese patients with IgG4-related disease (IgG4-RD) identified *HLA-DRB1* and *FCGR2B* regions as susceptibility loci [4]. Rs1340976 in *FCGR2B* showed an association with increased FCGR2B expression, the number of involved organs in diagnosis, and high serum IgG4 concentrations [4]. Other potential disease-susceptible genes encode cytotoxic T lymphocyte-associated protein 4 (*CTLA4*), tumor necrosis factor-α (*TNFA*), Fc receptor-like protein 3 (*FCRL3*), and cationic trypsinogen (*PRSS1*) [5–8].

Parallel Immune Response

Two parallel immunological responses are suspected to underlie the pathophysiology of type 1 AIP; one is a proinflammatory, tissue-destructive process characterized by the expansion of particular subsets of lymphocytes, while the other is an anti-inflammatory feedback response (Fig. 69.1) [9].

Autoantigen

The proinflammatory process is supposedly triggered by autoantibodies against autoantigens. Recent nonbiased global analyses identified annexin A11, laminin 511-E8, galectin-3, and prohibitin as potential autoantigens in type 1 AIP and IgG4-RD [10–13]. Other possible autoantigens identified by earlier targeted studies include carbonic anhydrase II, lactoferrin, pancreatic secretory trypsin inhibitor, and trypsinogens PRSS1 and PRSS2 [14,15].

T cells

Among the T-cell subsets, T helper 2 (Th2) cells and regulatory T cells (Tregs) are activated in this condition, with the Th1/Th2 balance shifting in favor of Th2 [16,17]. However, the Th1 reaction is not fully suppressed [18]. The expression of IFN-γ in the tissues of type 1 AIP is similar to that in those of primary sclerosing cholangitis and primary biliary cholangitis, while the expression of Th2 cytokines (e.g., IL-4, IL-5, IL-13, and IL-21) is markedly stronger in type 1 AIP, with a large number of IL-4+ lymphocytes infiltrating the pancreas [16]. The proportions of Tregs are also increased in both tissue-infiltrating lymphocytes and peripheral blood mononuclear cells [16,19].

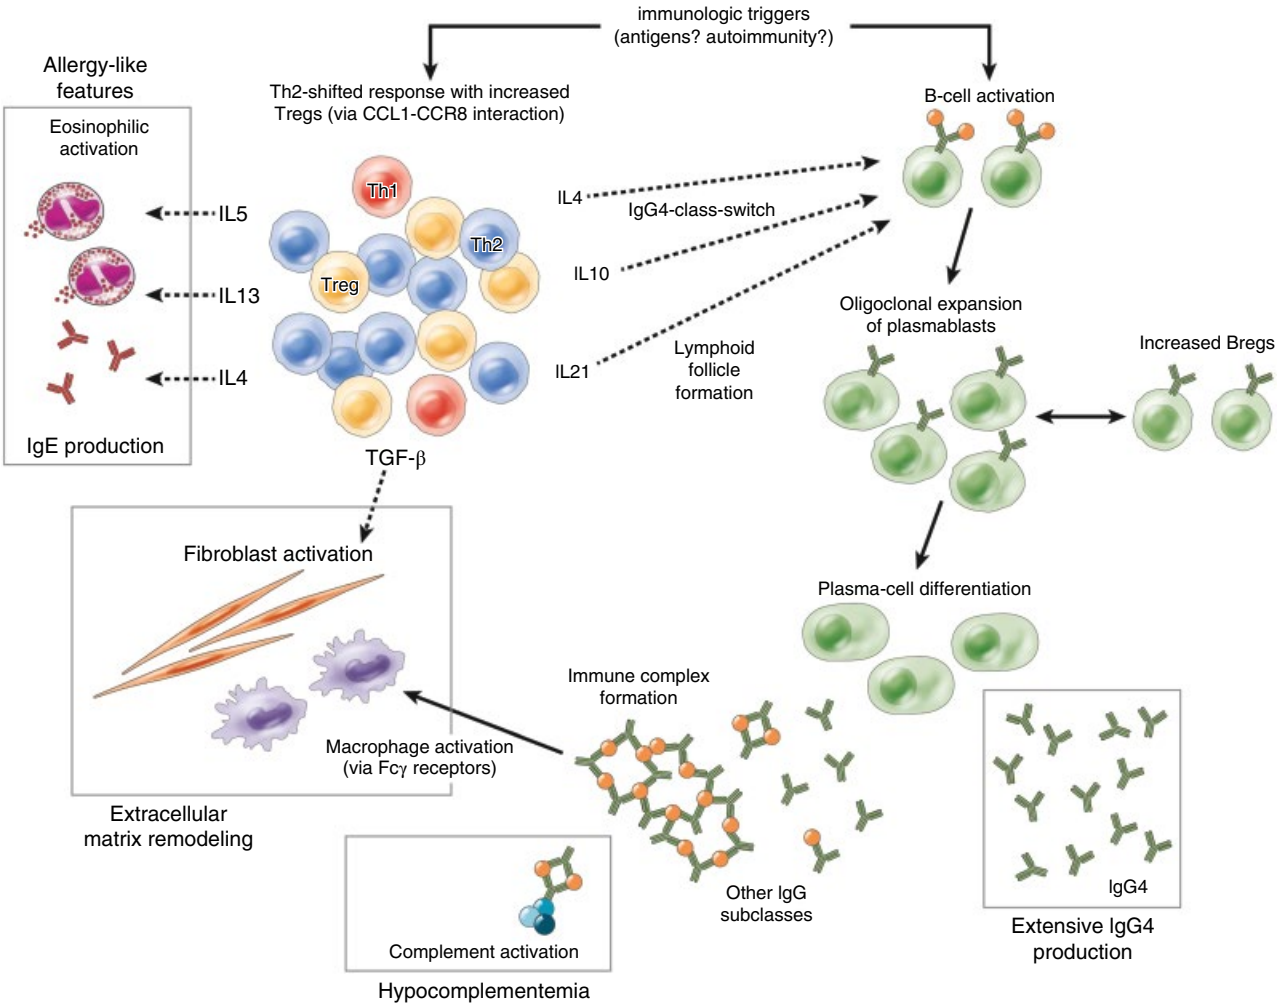

Figure 69.1 Proposed immunologic interactions in type 1 AIP. *Source:* Adapted from [9].

A T-cell subset involved in maturation and class-switching of B cells in germinal centers is known as T follicular helper (Tfh) cells. In IgG4-related disease, Tfh type 2 (Tfh2) cells are particularly expanded with the circulating Tfh2 cell counts positively correlated with the number of affected organs, disease activity, and serum IgG4 concentrations [20,21]. An *in vitro* study demonstrated that B cells co-cultured with patient-derived Tfh cells produce IgG4 [20]. Corticosteroid therapy decreases serum concentrations of IgG4 and IL-4, but does not affect the total number of circulating Tfh2 cells, which may initiate immune reactions at the time of relapse [20].

The potential involvement of CD4+ cytotoxic T lymphocytes (CTL) in IgG4-RD has been examined mainly in extrapancreatic organs. CD4+ CTL express granzyme A, IFN-γ, IL-1β, and TGF-β1. Next-generation sequencing of the T-cell receptor β chain gene revealed prominent clonal expansions of CD4+ CTL but not CD4+ memory Th2 cells in patients with IgG4-RD [22]. Infiltration of CD4+ CTL was also demonstrated by multi-color immunohistochemistry [23]. The ratio of CD4+ CTL among infiltrating lymphocytes in IgG4-RD is higher than that in other conditions; the ratio is also correlated with serum IgG4 concentrations and the number of affected organs. Another tissue study revealed that an increased number of HLA-DR-positive mesenchymal cells undergo apoptotic cell death in IgG4-RD [24]. Taken together, the expanded CTL may target the mesenchymal cells, leading to fibrosis and tissue remodeling.

Cytokines and Chemokines

Various types of cytokines are known to be expressed in type 1 AIP and IgG4-RD. Th2 cytokines such as IL-4, IL-5, and IL-13 supposedly contribute to tissue or serum

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. eosinophilia and elevated serum IgE levels, which are sometimes observed in patients with type 1 AIP [25,26]. IL-10, a cytokine produced by Tregs or macrophages, is also strongly expressed in type 1 AIP (Fig. 69.2) [16,17]. The combination of IL-4 and IL-10 may be relevant to the production of IgG4 because IL-4 induces the production of IgE and IgG4 from B cells and plasma cells, while IL-10 in addition to IL-4 suppresses the production of IgE, but selectively enhances that of IgG4 [27]. IL-21 is supposed to promote the interaction between B cells and Tfh2 cells at germinal centres [28]. TGF-β, another regulatory cytokine, may play a central role in the fibrosing process of type 1 AIP.

The CCL1–CCR8 interaction appears to be crucial for the recruitment of Th2 cells and Tregs because 50% of Th2 lymphocytes and 60% of FOXP3+ Tregs express CCR8 [29]. CCL1 is expressed in the duct epithelium and endothelial cells, including those involved in obliterative phlebitis, in type 1 AIP [30]. CCL1+ sites are infiltrated by CCR8+ lymphocytes (Fig. 69.2). The CCL1–CCR8 interaction may create a microenvironment in which Th2 cells and Tregs are abundant, leading to the IgG4 class switch through IL-4 and IL-10. This immunologic reaction is also probably responsible for the characteristic histologic changes observed in type 1 AIP such as periductal inflammation and obliterative phlebitis.

B Cells

B-cell depletion therapy with anti-CD20 antibodies is effective for type 1 AIP, which highlights the crucial involvement of B cells in its pathogenesis [31]. The proportion of circulating plasmablasts increases in type 1 AIP, and decreases rapidly upon treatment. Expanded plasmablasts are mainly of the IgG4 type and oligoclonal in nature, with dominant clones varying among

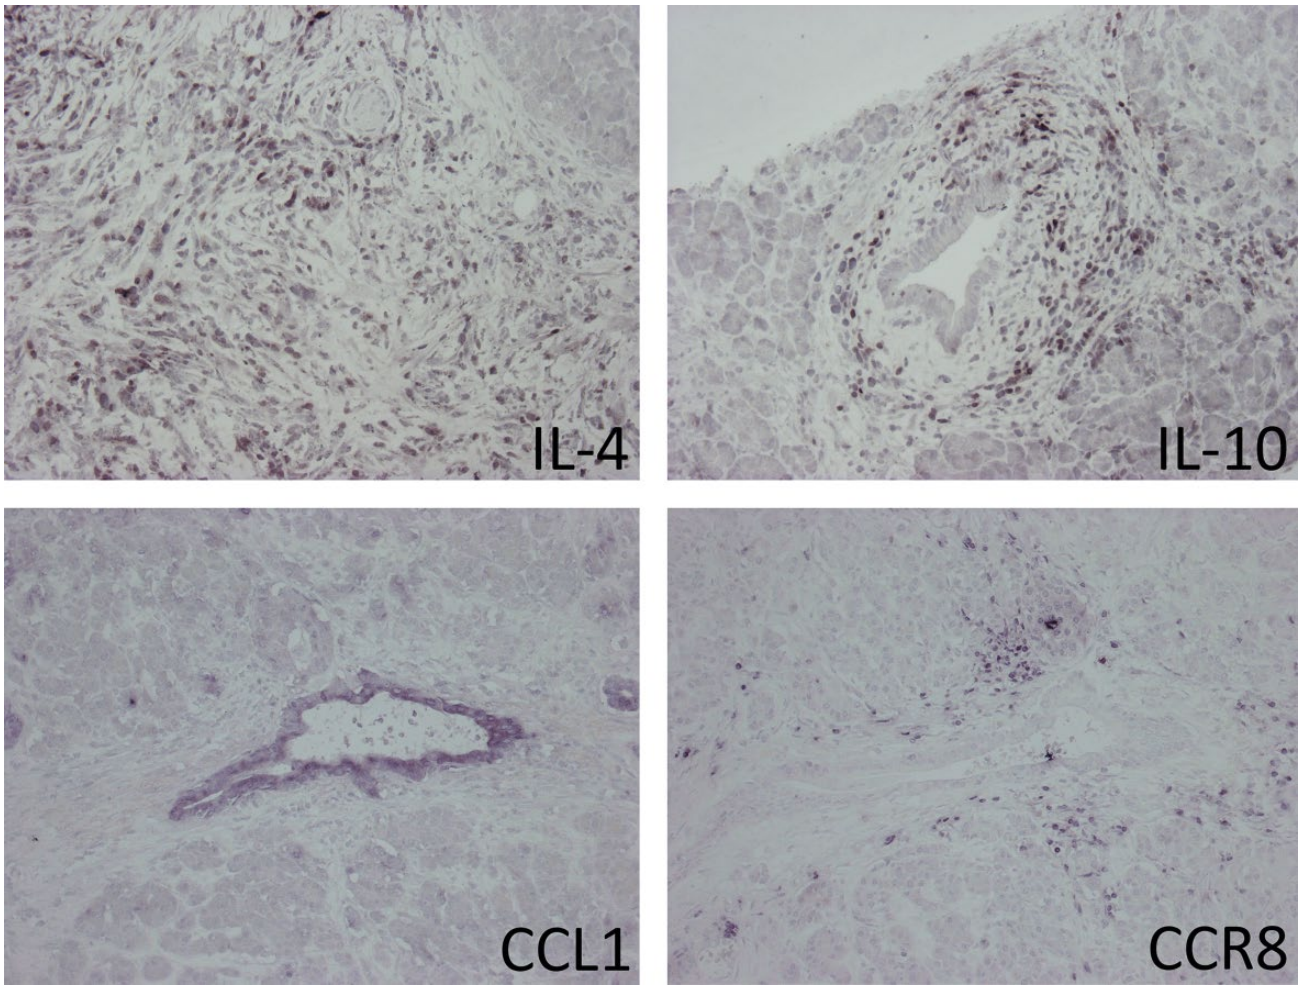

Figure 69.2 Immunologic factors expressed in type 1 AIP (*in situ* hybridization). Lymphocytes expressing IL-4 or IL-10 are observed. The pancreatic duct positive for CCL1 is surrounded by CCR8+ lymphocytes. *Sources:* (Upper panels) Zen et al. (2013) / Reproduced with permission of Elsevier. (Lower panels).

patients [32]. Similarly, tissue-resident and circulating IgG4-switched B cells in type 1 AIP are oligoclonal [33].

Role of IgG4

IgG4 generally has an anti-inflammatory property because of its relative inability to fix complement and its poor capacity to bind to Fc receptors [34]. This minor IgG subclass also has the unique ability to exchange a pair of heavy and light chains (the "Fab-arm exchange") [35]. This immunologic process causes IgG4 molecules to lose their antigen cross-linking ability, behave as monovalent antibodies, and become incapable of forming large immune complexes. Based on these anti-inflammatory characters of IgG4 molecules, the disease may be driven by other immunoglobulin subclasses, while IgG4 is secondarily induced in order to suppress inflammatory reactions in type 1 AIP.

A similar discussion will also be applied to hypocomplementemia, which is observed in ~40% of patients, particularly those with renal involvement [36]. Among the three complement activation systems, the classical pathway is predominantly activated in type 1 AIP. Since IgG4 cannot efficiently activate the classical pathway, complement fixation may be activated by other IgG subclasses, particularly IgG1, which fix complements more efficiently.

In a recent study, circulating IgG1 and IgG4 isolated from patients with type 1 AIP were subcutaneously injected into neonatal mice aiming to demonstrate the tissue reactivity of patient-derived immunoglobulins [37]. Injection of either IgG1 or IgG4 led to pancreatic injury with histologic evidence of stromal edema, acinar necrosis, hemorrhage, and the infiltration of polymorphonuclear leukocytes. The degree of tissue damage was higher with IgG1. Interestingly, the tissue injury led by IgG1 was suppressed by the simultaneous injection of patient-derived IgG4. It is the first objective finding indicating that IgG4 may behave in an anti-inflammatory manner in type 1 AIP [37].

Fibrosis

Fibrosis is persistently observed across the early and late phases of type 1 AIP. A characteristic pattern of fibrosis in type 1 AIP is referred to as storiform fibrosis. A unique feature of storiform fibrosis is the presence of abundant M2-type macrophages among collagen fibres. The number of myofibroblasts highlighted by immunohistochemistry is smaller in storiform fibrosis than in nonspecific granulation tissue or scarring fibrosis [38]. Therefore, storiform fibrosis represents a macrophage-rich, fibroblast-poor tissue reaction. This unique composition may explain the dramatic response to corticosteroids despite the fibrotic appearance.

Immune reactions underlying the macrophage induction in type 1 AIP remain unknown. Innate immunity (e.g., toll-like receptor) or cytolines are known to induce various types of macrophages. In addition, interaction between immune complexes and Fc receptors is another potential inducer of macrophages. A robust proteomic study with phosphopeptide enrichment methods identified that the immunologic pathway activated most significantly in type 1 AIP compared to primary sclerosing cholangitis is Fc-γ receptor-mediated phagocytosis [39]. This signal cascade occurring inside macrophages is initiated by the interaction between IgG molecules and Fc-γ receptors on the cell membrane. Since the capacity of IgG4 to bind to Fc receptors is poor [34], this signal pathway may be activated by IgG subclasses other than IgG4. However, several studies indicated that IgG4 molecules are capable of inducing M2 macrophages [40]. Although fibrosis in chronic inflammatory conditions is generally regarded as a consequence of the proinflammatory process, storiform fibrosis may be induced by IgG4 and therefore potentially represents an anti-inflammatory property in type 1 AIP.

Type 2 Autoimmune Pancreatitis

The rarity of this condition as well as the lack of serologic and immunologic biomarkers has restricted our investigations on the pathogenesis of type 2 AIP. A single potential clue is that one-third of patients have inflammatory bowel disease, particularly ulcerative colitis [41,42].

In our previous study, the immunopathologic features of type 2 AIP were compared with those of type 1 AIP and ulcerative colitis [43]. Quantitative PCR using mRNA extracted from pancreatic tissues revealed the markedly higher expression of IL-8 in type 2 AIP than in type 1 AIP. The expression of other cytokines (e.g., IFN-γ, IL-4, IL-10, and TNF-α) was similar in types 1 and 2 AIP or weaker in type 2 AIP. Immunostaining revealed that IL-8 was mainly expressed in the damaged duct epithelium, infiltrating neutrophils, and lymphocytes, with its expression being particularly strong around injured ducts (Fig. 69.3). This expression pattern of IL-8 was not observed in other forms of pancreatitis. Since IL-8 is a chemotactic factor for neutrophils, its aberrant expression in pancreatic ducts may underlie pathognomonic duct-centered, neutrophil-rich inflammation, known as granulocytic epithelial lesions (GEL), in type 2 AIP [42].

A similar expression pattern of IL-8 was also observed in colonic biopsies of active ulcerative colitis. IL-8 appeared to be aberrantly expressed in the crypt epithelium, particularly at sites of cryptitis and crypt abscesses [43]. The colonic epithelium was largely

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 69.3 IL-8 expression in type 2 AIP. Single immunostaining shows the extensive expression of IL-8 in pancreatic tissue. On double immunostaining, IL-8 (red) appears to be expressed in infiltrating inflammatory cells and pancreatic ducts that are also positive for cytokeratin (CK, green).

negative for this immunologic marker in infectious colitis, another form of neutrophil-rich enteritis. These findings indicate that IL-8 is one of the key molecules involved in the pathogenesis of type 2 AIP, and also suggest a pathogenetic link between type 2 AIP and ulcerative colitis.

The pancreatic duct epithelium in type 2 AIP was also demonstrated to aberrantly express programmed death-ligand 1 (PD-L1) [44]. The positive immunoreactivity was identified in 70% of cases of type 2 AIP, while it was not observed in type 1 AIP or other forms of pancreatitis [44]. This finding was observed in not only damaged ducts but also nonaffected epithelium. Although this unique finding has a diagnostic value, the immunologic significance remains unclear. The expression of PD-L1 did not correlate with the number of immune cells positive for programmed death 1 (PD-1) or CD8 [44].

Clinical Manifestation of Type 1 Autoimmune Pancreatitis

Tooru Shimosegawa

South Miyagi Medical Center, Shibata, County, Miyagi, Japan

What Is Autoimmune Pancreatitis?

Autoimmune pancreatitis (AIP) is a type of chronic pancreatic inflammation; its pathogenesis is suspected to involve immune mechanisms [1]. Two subtypes are presumed; one is pathologically defined by lymphoplasmacytic sclerosing pancreatitis (LPSP) [2], and the other by idiopathic duct-centric pancreatitis (IDCP)/granulocytic epithelial lesion (GEL) [3,4]. Considering the clinically distinct features of each type, the Honolulu consensus in 2009, defined the former as type 1 and the latter as type 2 [5]. Since AIP type 1 is characterized by the elevation of serum immunoglobulins, especially IgG4, and by the infiltration of IgG4-positive plasma cells in the pancreas and the various extrapancreatic lesions, this type is regarded as a manifestation of pancreatic involvement in the systemic disorder called "IgG4-related disease (IgG4-RD)," which is characterized by an overproduction of IgG4 due to some sort of immune abnormality [6].

In contrast, as AIP type 2 lacks biomarkers, including immunoglobulins, and shows unique pathologic findings in the pancreas characterized by the infiltration of granulocytes, there is a need for continued discussion on whether or not type 2 is truly caused by an autoimmune mechanism [7]. AIP type 1 corresponds to the concept of autoimmune pancreatitis proposed by Yoshida et al. in 1995 [8], and resembles chronic inflammatory sclerosis of the pancreas introduced by Sarles et al. in 1961 [9]. AIP type 1 is reportedly the dominant type of AIP in East Asia, whereas AIP type 2 is more frequently observed in Western countries [5,10].

The Clinical Features of AIP Types 1 and 2

Herein, I summarize the clinical features of AIP types 1 and 2, which were presented chiefly in the reports published before the third edition of *The Pancreas* [11–19].

Patients Profiles and Symptoms

AIP type 1 tends to develop in elderly male subjects with painless jaundice or mild abdominal pain, but acute pancreatitis is rare or less frequent at the onset compared to AIP type 2. Occasionally, asymptomatic patients are incidentally diagnosed based on characteristic findings on imaging, serology and the presence of extrapancreatic lesions. AIP type 2 presents more frequently with acute pancreatitis in younger populations, with no gender predilection. Obstructive jaundice is seen less frequently in type 2 AIP than in type 1 AIP. Approximately 30–50% of patients with type 1 AIP develop diabetes mellitus (DM) as a complication, but this percentage is lower in type 2 patients.

Imaging

Characteristic imaging findings in AIP types 1 and 2 include enlargement of the pancreas and irregular narrowing of the main pancreatic duct (MPD), which are common features of both types. The pancreas shows diffuse (>2/3 of the entire pancreas), segmental (1/3–2/3), or focal (<1/3) enlargement. Care should be taken when differentiating atypical AIP cases that show mass-like

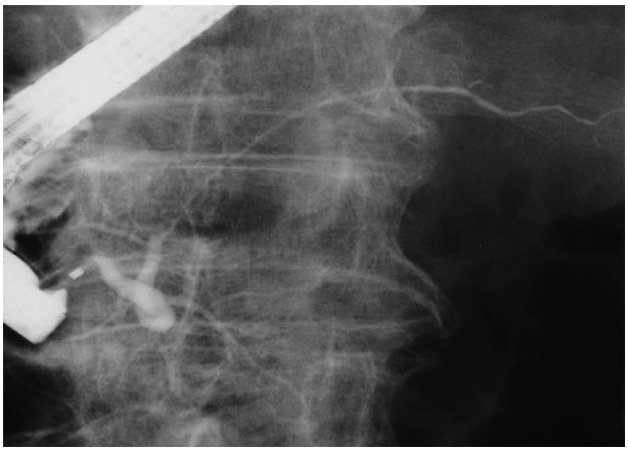
lesions, as in cases of focal pancreatic swelling, from pancreatic cancer.

A typical finding on abdominal ultrasound (US) is a diffusely swollen, hypoechoic "sausage-like" pancreas (Fig. 70.1a). Focal swelling or a tumor-like appearance was observed as a homogeneous hypoechoic mass with distinct margins. The characteristic feature of contrast-enhanced computed tomography (CT)/magnetic resonance imaging (MRI) is a delayed enhancement of the pancreas, which denotes gradual enhancement of the pancreatic parenchyma in the late phase on dynamic CT/MRI. A low-density or low-signal intensity peripheral band-shaped structure called "capsule-like rim" is sometimes seen on dynamic CT/MRI, which is considered highly specific to AIP (Fig. 70.1b). The inflammatory lesion in the pancreas showed a strong signal intensity on diffusion-weighted MRI. Positron emission tomography (PET) scans demonstrate the heavy accumulation of ^{18}F-fluorodeoxyglucose in the pancreas in both types of AIP and extrapancreatic lesions in AIP type 1, making it easy to understand the pathological extension.

Endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography (MRCP) showed diffuse, segmental, focal, or occasionally multiple narrowing of the MPD (Fig. 70.2). MPD narrowing in AIP can be differentiated from the short and severe stricture seen in pancreatic cancer by long-segment irregular narrowing in the AIP. In addition, AIP demonstrates slight dilatation of the duct upstream from the narrowed segment, which may help differentiate its duct stricture from that of pancreatic cancer, which usually shows severe dilatation in the upstream MPD.

Serological Findings

Most patients with AIP type 1 show elevated serum γ-globulin, IgG, and IgG4 levels, and high serum IgG4 levels are characteristic features of AIP type 1. Antinuclear antibody (ANA) and rheumatoid factor are often positive, and various autoantibodies such as carbonic anhydrase II, lactoferrin, pancreatic secretory trypsin inhibitor, lipase, and amylase α-2A occasionally present nonspecific positive results. A recent study suggested that laminin 511-E8 may be a specific autoantigen in some patients with AIP type 1 because patients' serum IgG binds to laminin in the diseased area of the



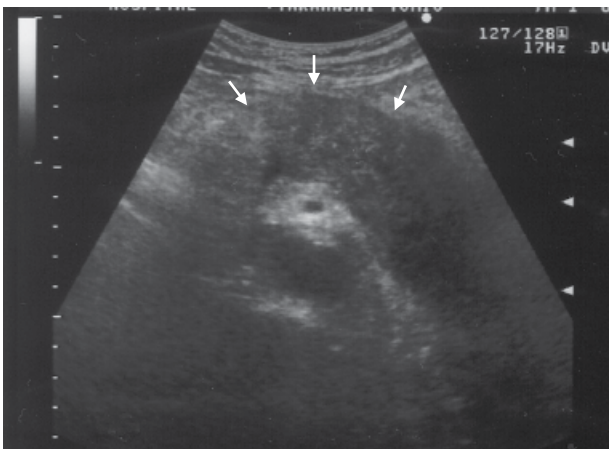


Figure 70.2 The patient showed diffuse and irregular narrowing of the main pancreatic duct on endoscopic retrograde pancreatography (ERP).

(a)

(b)

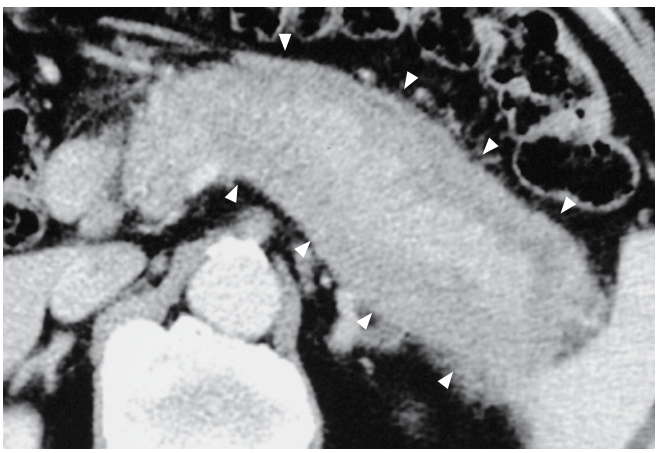

Figure 70.1 (a) Typical US imaging of the "sausage-like" pancreas observed in a patient with type 1 AIP. The entire pancreas swells diffusely (white arrows) and shows internal hypoechoic pattern with scattered hyperechoic spots. (b) The late-phase imaging of swollen pancreas of the same patient on CECT. The pancreas shows diffuse enlargement called "sausage-like" and the parenchyma of swollen pancreas demonstrates characteristic delayed enhancement with a low-density rim-like structure in the periphery of the pancreas (capsule-like rim: white arrowheads).

pancreas [20]. Anti-laminin 511-E8 antibody can be detected in approximately 50% of Japanese patients with AIP. The presence or absence of the antibody may be related to the phenotype of type 1 AIP, such as the location of pancreatic involvement and the association with malignant or allergic diseases [20]. Serum complements show low titers in some patients with AIP type 1, especially when they are complicated with renal lesions. In contrast, no specific biomarkers have been identified for AIP type 2, including elevated serum γ-globulin and immunoglobulins.

Histopathology of the Pancreas

The histopathologic definition of AIP type 1 is LPSP [2]. Abundant lymphocytes and IgG4-positive plasma cells infiltrate the pathological lesion of the pancreas, which is especially dense around medium and small ducts. These infiltrates compress the ducts while keeping the epithelium intact. LPSP is also characterized by severe and characteristic fibrosis called storiform fibrosis and obliterative phlebitis (Fig. 70.3a, b). Eosinophil infiltration can be seen in some patients, but granulocytes are principally absent.

AIP type 2 is pathologically defined as IDCP/GEL [3,4]. It is characterized by the infiltration of granulocytes around ducts and in acini, sometimes associated with GEL [4], infiltration of granulocytes into the duct lumen, and duct epithelium with the destruction of the epithelium. These findings are considered more specific if present in and around the interlobular ducts.

Extrapancreatic Lesions

AIP type 1 is characterized by the presence of various extrapancreatic lesions. The pathologic characteristics of the extrapancreatic lesions resemble the lesions in the pancreas, including the infiltration of numerous IgG4-positive plasma cells. Representative extrapancreatic lesions include sclerosing cholangitis (involvement of intrahepatic or hilar hepatic bile duct, and/or intrapancreatic bile duct), sclerosing dacryosialoadenitis (symmetrically swollen upper eyelid lacrimal glands and/or submandibular glands, which are painless, smooth-surfaced, elastic hard nodules or masses), retroperitoneal fibrosis (marked fibrosis in retroperitoneal tissue), and renal lesions (tubulointerstitial nephritis with various imaging findings on contrast-enhanced CT (CECT) such as multiple enhancement defects in the renal cortex, mass-like appearance, or swelling of the kidney). Less frequent or rare lesions reported to date include pulmonary diseases (nodular lesions or interstitial pneumonitis), aortitis (inflammatory aneurysms in the abdominal or thoracic aorta), inflammatory pseudotumors, hypophysitis, chronic thyroiditis, mediastinal or abdominal lymph node swelling, swollen duodenal papilla, prostatitis, autoimmune thrombocytopenia, autoimmune neurosensory hearing loss, uveitis, Henoch-Schönlein purpura. In addition, irritable bowel disease (IBD) can be a complication even in patients with type 1 AIP; however, it is rare or less frequent compared with type 2 AIP. In contrast, IBD, especially ulcerative colitis (rather than Crohn's disease), complicates approximately 30% of type 2 AIP cases, whose patients usually

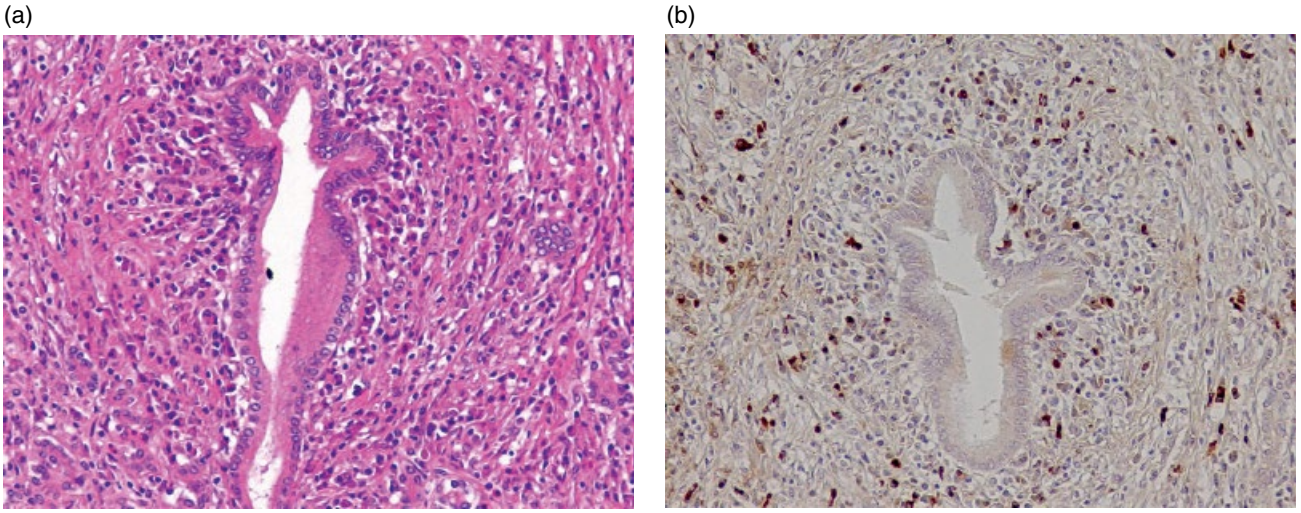

Figure 70.3 (a) Hematoxylin-eosin stained tissue section showed dense lymphoplasmacytic infiltration and strong fibrosis called "storiform fibrosis" around the duct while preserving the duct epithelium intact. (b) Immunostaining for IgG4 revealed aggregation of numerous IgG4-positive plasma cells chiefly around the duct.

lack the wide array of extrapancreatic lesions seen in patients with type 1 AIP.

Response to Steroids and Relapses

Although patients with both AIP types 1 and 2 show excellent responses to steroids and clinical symptoms, signs, imaging findings, and pathologic findings improve quickly and remarkably, the high rate of relapse is a problematic feature of type 1 AIP. Relapse typically does not occur or is present less frequently in type 2 AIP than in type 1 AIP.

Long-Term Prognosis

The long-term prognosis of patients with type 1 AIP is relatively good, and it has been reported that their 5-year survival rate is not different from the background population [11]. Patients with type 2 AIP also show a fairly good prognosis, and their 5-year survival rate is similar to that of patients with type 1 AIP. However, it is also known that patients with type 1 AIP develop intraductal stones, parenchymal atrophy, and frequent pancreatic exocrine insufficiency during long-term follow-up, showing clinical findings similar to those seen in advanced chronic pancreatitis [21–23]. In addition, some reports suggest higher rates of malignant diseases, including pancreatic cancer, during the clinical course of type 1 AIP [24–27].

Typical Features of AIP Type 1 (Example of Japanese AIP Patients)

Japanese people are roughly of a single race and are considered ethnically homogeneous. It is well known that AIP type 1 is the dominant type in Japanese patients with AIP, whereas type 2 is extremely rare. Recently, a nationwide survey of patients in 2016 diagnosed using the clinical diagnostic criteria for AIP 2011 (JPS 2011) was conducted in Japan [28,29]. The diagnostic criteria used in the study were modified from the ICDC [30] to diagnose type 1 AIP specifically and more concisely [31]. Here, we summarize the results of the latest nationwide survey in Japan and introduce the clinical features of Japanese patients with AIP as a typical example of type 1 AIP.

According to the results [29], the estimated number of Japanese patients with AIP was 13,436 annually (prevalence rate of 10.1/100,000 population), and the estimated number of new patients was 3984 annually (incidence rate of 3.1/100,000 population). The nationwide survey was conducted three times (in 2002, 2007, and 2011), and the number of patients increased in every survey. The estimated number of patients with AIP in 2016 was 7.9 times higher than the 1700 patients identified in the 2002 nationwide survey.

In the survey, 1474 patients with AIP were identified by a secondary survey, and their clinical features were examined in detail (Table 70.1). The male-to-female ratio was male-dominant at 2.94, and the average age was 68.1 years. Most male patients were aged in their seventies, whereas female patients were in their sixties.

Among the patients examined, 62.8% were symptomatic, with jaundice observed in nearly half of the patients (48.6%), followed by abdominal pain (25.6%), and weight loss (3%); however, acute pancreatitis was rare (0.9%). Pancreatic enlargement was observed in 96.5% of the patients, among which diffuse enlargement was observed in 47.2%, segmental swelling in 28.0%, and focal swelling in 19.7%; however, atypical findings such as a tumor-like appearance were noted in only 0.8% of patients. MPD narrowing was observed in 87.5% of the patients, with diffuse, segmental, focal, and multiple narrowing in 34.4%, 30.9%, 17.8%, and 2.6%, respectively. Calcification of the pancreas was detected in 5.9% of patients. Elevation of serum IgG4 (≧135 mg/dL) was seen in 84.5% of the patients, the elevation of serum IgG in 58.5%, ANA-positivity in 32.6%, and rheumatoid factor in 18.3% of the patients.

Extrapancreatic lesions were complications in 60% of the patients, most frequently observed as sclerosing cholangitis in 48.6% (hepatic hilum, 12.9%; intrapancreatic bile duct, 40.9%), sclerosing dacryosialadenitis in 33.3%, retroperitoneal fibrosis (RF) in 17.1%, renal involvement in 8.4%, lung lesions in 8.4%, IBD in 2.5%, and inflammatory pseudotumors in 1.6%. Steroids were administered to 84.4% of the patients, and 98.6% showed good responses. However, relapse occurred in 23.4% of the patients, with accumulating relapse rates of 14% at 3 years, 25% at 5 years, 40% at 10 years, and 50% at 15 years after the commencement of steroids. Although malignant tumors, including gastric, colon, and prostate cancers developed during the clinical course in some patients, the overall prognosis was fair, and the survival rate was 97.3%, at 2 years after the start of the survey.

Global AIP Type 1

The results of a multicenter study on patients with AIP conducted by 15 centers in 8 countries were reported in 2011 [12]. In this study, the clinical features of 204 patients with histologically confirmed LPSP and 64 with IDCP were compared. As shown in (Table 70.1), the patients with LPSP, the histologic definition of AIP type 1, had a mean age of 61.6 years, with a male-dominant

male-to-female ratio of 2.84, and had symptoms including jaundice in 75% of the patients, abdominal pain in 41%, and acute pancreatitis in only 5%. In addition, diffuse enlargement of the pancreas was noted in 40% of the patients, elevated serum IgG4 in 63%, association of extrapancreatic lesions in 45%, sclerosing cholangitis at the hepatic hilum in 29%, sclerosing dacryosialadenitis in 12%, and IBD in only 2%. Steroids were administered to 44% of the patients, showing good responses in all patients, but relapse occurred in 36%.

The clinical features of the patients with LPSP shown in this study resembled those of 1474 patients analyzed in the Japanese nationwide survey in 2016 [29], but differed from those of the patients with IDCP in the same study (Table 70.1) [12]. In that report, the clinical features of 463 AIP patients without histologic confirmation were also studied according to their respective nations [12]. As a consequence, the clinical features of the patients in Asian countries diagnosed by the Asian criteria [32] and those of the patients in the United States, India, and the United Kingdom diagnosed by the HISORt criteria [33] showed characteristics similar to those of patients with histologically confirmed LPSP. In contrast, the German patients diagnosed by the Mannheim criteria [34] and the Italian patients diagnosed by the Italian criteria [35] showed clinical features partly resembling type 2 AIP, suggesting the influence of diagnostic criteria employed on the clinical features of AIP.

By country, 52 histologically confirmed Korean patients with AIP types 1 and 2 in 2012 [14], and 706 Chinese patients with AIP diagnosed by various criteria in a multicenter study in 2015 were evaluated [36]. The clinical features of AIP patients clarified in these studies resembled those of the histologically confirmed LPSP patients reported in an international multicenter study [12], suggesting the dominance of AIP type 1 in both countries (Table 70.1). In addition, the clinical features of AIP type 1 (LPSP) and type 2 (IDCP) patients diagnosed by the ICDC or histology were studied in the United States [11] and in various European countries, including the Netherlands [37], Spain [38], Italy [39], and Germany [40], confirming that the clinical features of AIP type 1 (LPSP) patients in the Western countries were fundamentally not different from those of Asian patients (Table 70.1). A report from a single institute in Sweden [41] showed somewhat different results from the typical clinical features of AIP type 1, even in patients diagnosed with type 1 by the ICDC or histology, such as younger age, no sex difference, greater frequency of acute pancreatitis onset, and lower rates (less than half) of serum IgG4 elevation. Therefore, a prospective multicenter study involving various countries may be required to clarify whether the differences originate from ethnicity or other factors.

AIP Type 1 and IgG4-RD

Kamisawa proposed a new disease concept, "IgG4-related sclerosing disease," in 2003 [42].

He considered AIP type 1 a systemic fibrous disease characterized by the overproduction of IgG4 and infiltration of abundant IgG4-positive plasma cells in various organs. Various nomenclatures have been proposed for the disease, such as "systemic IgG4-related plasmacytic syndrome (SHIPS)" [43] by a group of researchers who considered sclerosing dacryosialadenitis, which used to be called Mikulicz disease, as its representative, and "IgG4-related multiorgan lymphoproliferative syndrome (IgG4-MOLPS)" [44] considering it as an IgG4-positive plasma cell proliferative disease. Thereafter, the name was unified as "IgG4-related disease (IgG4-RD)" [45], which is now commonly used worldwide. IgG4-RD includes IgG4-related sialadenitis (IgG4-Mikulicz), IgG4-related ophthalmic disease, IgG4-related pachymeningitis, IgG4-related hypophysitis, IgG4-related pulmonary diseases, AIP type 1, IgG4-related sclerosing cholangitis (IgG4-SC), IgG4-related kidney disease, RF, inflammatory pseudotumor, inflammatory periaortitis, and periarteritis [45].

Comprehensive diagnostic criteria for IgG4-RD were proposed in 2011 [46], partly revised in 2020 [47], and they have been used to screen patients to diagnose IgG4-RD. However, as the comprehensive criteria, both original and revised, depend heavily on histologic findings for the diagnosis, it is necessary to use other criteria that are more specific to AIP [30], IgG4-SC [48], IgG4-Mikulicz [49], IgG4-related ophthalmic disease [50], IgG4-related kidney disease [51], IgG4-related respiratory disease [52], and IgG4-related periaortitis/periarteritis and RF [53] when the acquisition of histologic specimens is difficult or confirmation of the diagnosis is required.

Recently, it has been suggested that IgG4-RD could be categorized into three groups according to the distribution of diseased organs on either side of the diaphragm [54]: head and neck IgG4-RD (HN IgG4-RD), pancreatobiliary IgG4-RD (PB IgG4-RD), and diffuse IgG4-RD. In comparison with PB IgG4-RD, HN IgG4-RD showed manifestations more frequently on the rostral side of the diaphragm, including the orbital, lacrimal gland, submandibular, parotid gland, asthma, and sinusitis, whereas lung manifestations were similar. When compared with HN IgG4-RD, PB IgG4-RD showed manifestations more frequently on the caudal side of the diaphragm, represented by the pancreas and biliary manifestations, whereas renal lesions were similar. Interestingly, compared with HN IgG4-RD, PB IgG4-RD patients were older, more frequent in males, and showed a shorter duration of follow-up.

These findings suggest that IgG4-RD tends to develop a cluster of involved organs on either side of the diaphragm and extend from there to systemic manifestations with increased disease activity. It is interesting to study whether HN and PB IgG4-RD are different subsets of IgG4-RD and whether the difference in the phenotypes is caused by genetic background or by immunologic response to heterogeneous autoantigens.

Clinical Manifestation of Type 2 Autoimmune Pancreatitis

Nicolò de Pretis and Luca Frulloni

Department of Medicine, Gastroenterology Unit, Pancreas Center, University of Verona, Verona, Italy

Introduction

Autoimmune pancreatitis (AIP) is a fibroinflammatory disease of the pancreas that has attracted increasing interest [1]. Two distinct entities, type 1 and type 2, have been defined histologically under the unifying term AIP [2]; the subtypes share symptoms, radiologic appearance, and a dramatic response to steroids. However, the subtypes clearly differ in terms of their pathologic features, the involvement of other organs, and clinical outcomes [3,4]. A histologic diagnosis of AIP subtypes is not always achievable. The introduction of the International Consensus Diagnostic Criteria (ICDC) [3], based on the combination of five cardinal criteria (imaging, serology, other organ involvement, histology, and response to steroids), classified into level 1 (more reliable) and level 2 (less reliable), has enabled the diagnosis of disease subtype even in the absence of histology. ICDC introduced another type of disease, AIP not otherwise specified (NOS), if diagnosis of type 1 or 2 AIP cannot be achieved. Since there is no serologic marker for type 2 AIP, the diagnosis of this subtype remains much more difficult. This may explain why almost all the literature on AIP is focused on type 1 AIP, which is a part of IgG4-related disease and represents between 80% and 95% of all AIP cases [4]. Few studies have been published on type 2 AIP, and most of the available data have been extrapolated from small subgroups in studies focused on type 1 AIP.

Type 2 AIP remains an undefined, underestimated, and debated clinical entity. Consensus is lacking and controversies still surround this subtype of AIP [5].

Pathology

The first pathologic distinction of subtypes of AIP was published at the beginning of the twenty-first century [6,7]. Initially, descriptive pathologic terms were used to describe the subtypes of the disease, such as lymphoplasmacytic sclerosing pancreatitis (LPSP) and idiopathic duct-centric chronic pancreatitis (IDCP) [6]. Zamboni et al. [7] introduced the term "granulocytic epithelial lesion" (GEL) to identify patients with ICDP. The terms LPSP and ICDP were definitively replaced with type 1 and type 2 AIP, respectively [2], following the publication of the Honolulu consensus document in 2010.

Type 2 AIP is characterized by an inflammatory infiltrate mainly involving the pancreatic ductal system with a predominant neutrophilic component [2]. The most distinctive feature is the presence of GEL in medium- and small-size ducts, characterized by neutrophilic infiltrate in the epithelial layer of the pancreatic ducts (ICDC level 1), changes that may lead to the destruction and obliteration of the duct lumen (Fig. 71.1). GEL often also involve the acini (ICDC level 2). Intraductal clusters of neutrophils resembling crypt abscesses in IBD often coexist. Diffuse inflammation, obliterative phlebitis and storiform fibrosis, which are characteristic of type 1 AIP, are less prominent in type 2 AIP. The other distinctive feature of type 2 AIP is the scant presence (<10 cells/high-power field) or complete absence of IgG4-positive plasma cells on immunostaining.

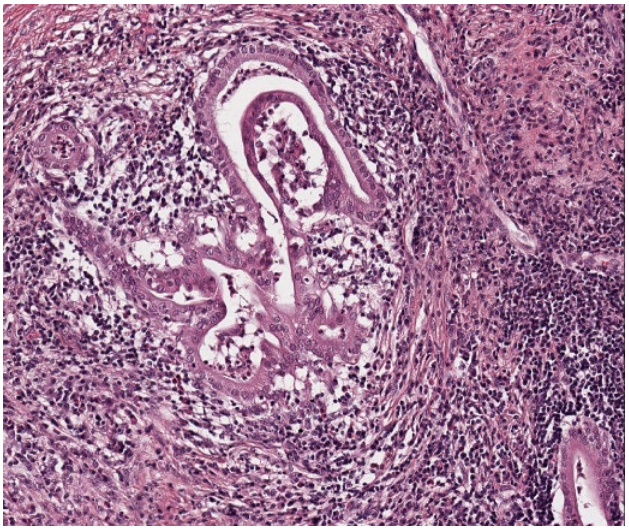

Figure 71.1 Histologic features of type 2 AIP: periductal lymphoplasmacytic cells infiltration with granulocytic epithelial lesion, characterized by the invasion of the ductal structures by neutrophilic granulocytes, with destruction of the duct epithelium (hematoxylin-eosin). *Source:* Image courtesy of Giuseppe Zamboni, Verona, Italy.

Epidemiology

The epidemiology of type 2 AIP is undefined, and no data are available about its incidence and prevalence.

Type 2 AIP is estimated to be a rare disease with a prevalence of 0.5/100,000 [5]. However, the probability of type 2 AIP might be higher in the pediatric population or in young patients (<40 years) with a previous history or synchronous diagnosis of IBD presenting with acute pancreatitis without etiologic factors (gallstone, alcohol, hypertriglyceridemia, genetics) [8,9]. Patients with type 2 AIP are generally in the third to fourth decade of life, with no gender preference, and they are significantly younger than patients with type 1 AIP, who are usually in the sixth or seventh decade of life and are predominantly male [10–15].

Type 2 AIP represents less than 10% of all AIP patients. The proportion of type 2 AIP is lower in Asia (3.7%) [16] and China (4.7%) [17] than in Europe (12.9%) [16], Italy (18%) [11], and North America (13.7%) [16]. However, the proportion of type 2 AIP is higher (28.8%) when considering patients with a histologic diagnosis of AIP [18].

The association with inflammatory bowel disease (IBD) as a diagnostic criterion [3] strengthens the relation between type 2 AIP and IBD. The concomitant presence of IBD has been described in 40–84% of patients with type 2 AIP [10–12]. Lorenzo et al. [19] published a retrospective case series of 91 patients with type 2 AIP and IBD, reporting ulcerative colitis (UC) and Crohn's disease in 58 (64%) and 33 patients (36%), respectively. Hart et al. [10] reported a higher proportion of UC (74%) compared to Crohn's disease (16%) among 19 patients with concomitant IBD and type 2 AIP.

In most cases, the clinical onset of IBD precedes or is concomitant with AIP. However, the development of IBD after AIP has also been described [10,20]. The diagnosis of IBD after diagnosis of AIP switches the diagnosis of AIP subtype from type NOS to type 2 [20].

Despite the high frequency of IBD in patients with type 2 AIP, the prevalence of type 2 AIP in patients with IBD seems to be quite low. A Korean study estimated a prevalence of AIP to be approximately 0.54% in 1106 patients with UC [21]. In a Japanese study, type 2 AIP was found in 5 out of 961 patients with UC (0.5%) and in 2 out of 790 patients with Crohn's disease (0.2%) [22]. However, a diagnosis of type 2 AIP was made in 52 out of 138 patients with IBD and pancreatitis (37.7%), histologically confirmed in 15 patients (10.8%), and based on Japanese criteria, "probable" in an additional 37 patients (26.8%) [23]. The prevalence of type 2 AIP in patients with IBD is probably underestimated, and the diagnosis of AIP needs to be considered in IBD patients with acute pancreatitis.

Clinical Profile and Symptoms

The clinical profile of type 2 AIP significantly differs from that of type 1 AIP [11,14,16,18]. Type 2 AIP is an organ-specific pancreatic inflammatory process, while type 1 AIP is one part of a systemic IgG4-related disease [24]. Therefore, symptoms correlated with the involvement of other organs might be observed in patients with type 1 AIP (e.g., retro-ocular infiltration) but not in patients with type 2 AIP. Acute pancreatitis is the most frequent presentation at clinical onset in patients with type 2 AIP (50–65%), while jaundice is less frequent (7–30%) [10,15]. Jaundice is related to biliary involvement (single biliary stenosis, distal) secondary to direct compression of the inflamed pancreatic tissue on the distal (intrapancreatic) common bile duct; this is in contrast to type 1 AIP, where biliary involvement (multiple stenoses, distal and proximal) is related to the direct involvement of the biliary tree wall by the IgG4-related inflammatory process. Other clinical manifestations of type 2 AIP are abdominal pain and, uncommonly, diabetes and steatorrhea.

A significant proportion of patients with type 2 AIP have concomitant IBD, mainly UC. Type 2 AIP generally develops in patients with a known history of IBD, but AIP might occur simultaneously with IBD or before the clinical onset of IBD [20]. However, the histologic and clinical features of UC associated with type 2 AIP seem to be quite different from "classical" UC [25].

Diagnosis

The diagnosis of type 2 AIP is based on the ICDC [3], and it is more difficult to achieve compared to the diagnosis of type 1 AIP because of the lack of a serologic marker.

The distinction between "definitive" and "probable" type 2 AIP was proposed by the ICDC to underline the strength of the diagnostic criteria and to overcome the need for histology for the diagnosis of type 2 AIP [3].

According to the ICDC, a "definitive" diagnosis of type 2 AIP based on histology is achieved only if GEL are detected at histology (Fig. 71.2). Indeed, the diagnostic criteria include the evidence of disease at imaging (typical – level 1; atypical – level 2) and the presence of GEL in the pancreatic ductal system (level 1) or GEL in the acini (level 2) together with an association with IBD and a response to steroids at imaging (Fig. 71.3). A definitive diagnosis of type 2 AIP is easily achieved on surgical specimens in patients who are improperly resected. In nonresected patients, histology might be achieved with EUS-guided tissue acquisition, but the detection of GEL is limited. Very few case reports have been published on the role of EUS-guided fine-needle biopsy (FNB) for the diagnosis of type 2 AIP, reporting rare cases of GEL identification in tissue specimens of the fork-tip needle [26].

If histology with GEL identification is lacking or inconclusive, a "probable" diagnosis of type 2 AIP can be achieved with evidence at imaging (typical – level 1; atypical – level 2) and an association with IBD and a response to steroids, that is, without histology (Fig. 71.2).

Radiologically, patients with type 2 AIP might have a typical diffuse (level 1) (Fig. 71.4) or atypical focal (level 2) (Fig. 71.5) involvement of the pancreatic gland, similar to patients with type 1 AIP. Indeed, it is not possible to distinguish between type 1 AIP and type 2 AIP by imaging [3,27]. The concomitant involvement of other organs at imaging, such as the kidney, retroperitoneum, lung, and proximal biliary tree, is suggestive of an IgG4-related disease and, therefore, of type 1 AIP.

The most specific radiologic appearance of type 2 AIP on CT and MRI scans (detectable in approximately 30–50% of patients) is a diffuse enlargement of the pancreas with loss of the normal lobulated contour (Fig. 71.4) [28,29]. The pancreas typically appears hypoenhanced in the early phase and hyperenhanced in the late phase after contrast medium (c.m.) administration. Moreover, a hypoenhanced capsule-like rim surrounding the pancreatic gland in the early phase after c.m. has been described in less than one-third of patients. Unfortunately, some patients present an atypical focal involvement of the pancreatic gland (ICDC level 2) with the detection of a hypodense (at CT-scan images) or hypointense (at T1-weighted MRI images) pancreatic mass that is hypoenhanced in the arterial phase [28–30]. The pancreatic mass is generally slightly hyperenhanced in the late portal phase in AIP, in contrast to pancreatic cancer. However, EUS-guided tissue sampling is strongly suggested in these patients, considering that the risk of pancreatic cancer is 10 times higher [31]. The introduction of new end-cutting forward-acquiring needles seems to increase the

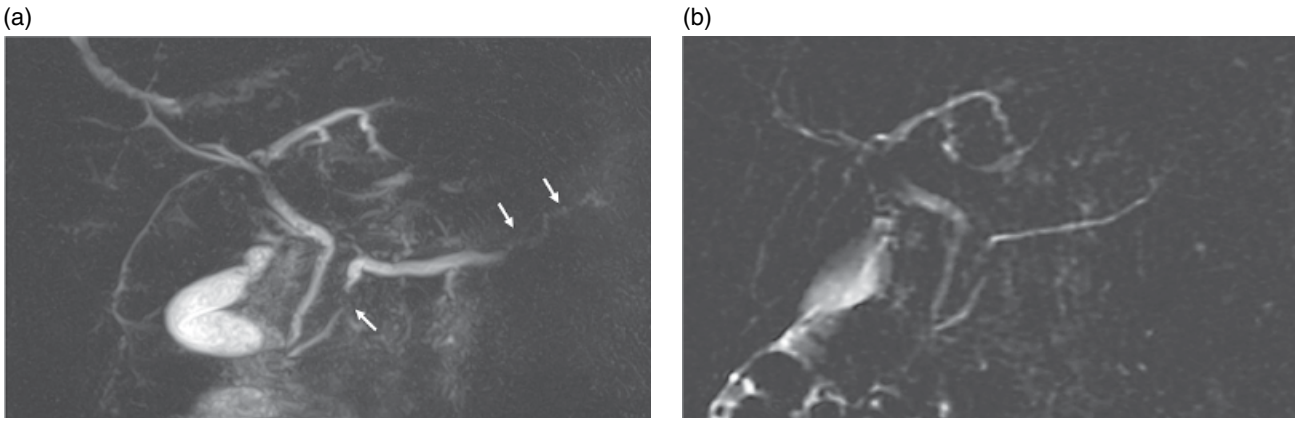

Figure 71.3 Magnetic resonance cholangiopancreatography (MRCP) of a patient with type 2 AIP. Before steroid treatment: (a) a short stricture of the main pancreatic duct in the pancreatic head (single arrow) with upstream dilation, with a second long stricture in the pancreatic tail (arrows). After steroid treatment (b) the main pancreatic appearance is normal.

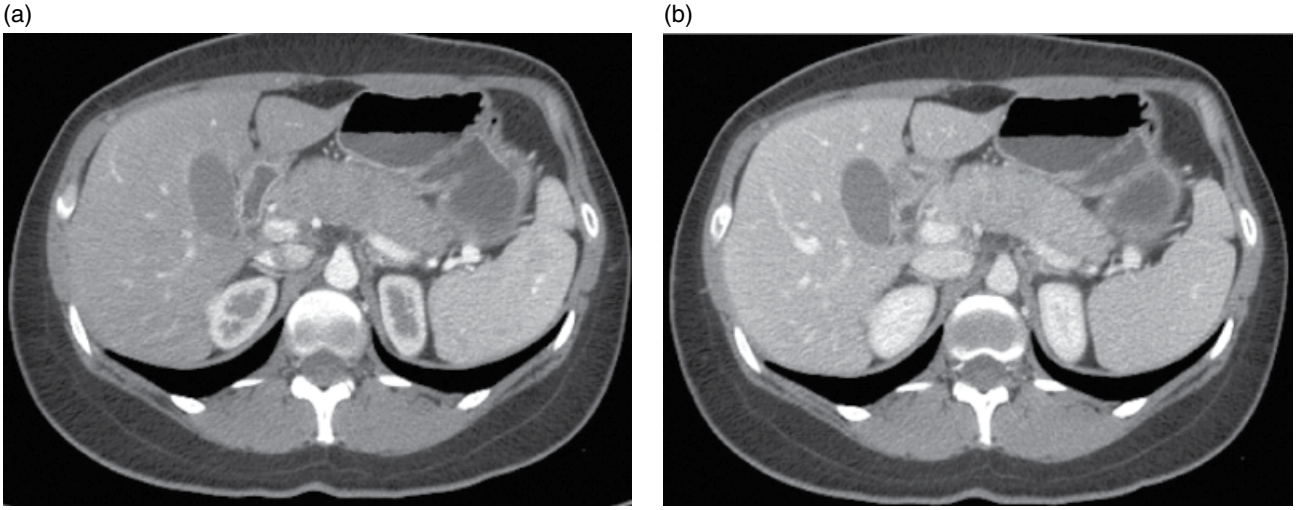

Figure 71.4 Contrast-enhanced computed tomography (CT) of a patient with diffuse type 2 AIP involving the body and tail of the pancreas. In the "early" arterial phase (a) the involved pancreas is hypoenhancing. In the "late" portal phase (b) it appears isoenhancing or slightly hyperenhancing. The main pancreatic duct is not visible in both images.

sensitivity and specificity of EUS-guided pancreatic biopsies in the diagnosis of pancreatic masses [31] Therefore, the new needles allow not only the exclusion of a cancer diagnosis, similar to what is possible with fine-needle aspiration cytology, but also the diagnosis of AIP.

Hart et al. [10] showed that patients classified as having "definitive" or "probable" type 2 AIP have similar clinical profiles and disease-related outcomes. Therefore, the distinction between "definitive" or "probable" type 2 AIP is not necessary in clinical practice.

Finally, considering that the presence of IBD allows for a diagnosis of type 2 AIP, and UC associated with type 2 AIP is often asymptomatic [25], the dosage of fecal calprotectin has been suggested as a screening test to select patients for colonoscopy with biopsy, even if asymptomatic [32].

Therapy and Risk of Relapse

The aim of AIP treatment is to relieve pancreatic pain and resolve jaundice by reducing inflammation, and treatment can possibly prevent disease relapse and progression toward chronic pancreatitis. Spontaneous remission of type 2 AIP has been described, even though further episodes of pancreatitis have been later observed in these patients [10,14]. Therefore, if a lot of time has

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 71.5 Contrast-enhanced magnetic resonance image (MRI) of a patient with focal type 2 AIP involving the head of the pancreas. In the "early" arterial phase (a) the presence of a hypoenhanced mass in the head of the pancreas (arrows). In the "late" portal phase (b) the involved pancreas appears isoenhancing.

elapsed from the last imaging (CT or MR), it is advisable to repeat the diagnostic investigation before starting therapy to avoid treating patients in spontaneous remission.

Medical treatment of type 2 AIP is based on steroids at the same dosage (0.6–1 mg/kg/day or 30–40 mg/day) proposed for the treatment of type 1 AIP [33]. Response rates to steroids are close to 100% but may reflect the need for "response to steroids" as a criterion for the diagnosis when histology is lacking. Steroids induce a quicker remission more consistently, and they reduce the probability of relapse compared to a conservative approach [34]. Differently from type 1 AIP, no alternative treatments have been proposed to induce remission in patients with type 2 AIP, even if responses to antitumor necrosis factor agents [19] and colchicine [35] have been reported in a few cases.

Response to treatment should be assessed within 2–4 weeks from initial steroid administration. In atypical focal forms of AIP, an absent or incomplete response is suggestive of an alternative diagnosis, and surgery is recommended if pancreatic cancer cannot be safely excluded [36].

After remission, steroid dosage can be reduced by 5 mg every 1–2 weeks up to suspension.

Relapse in patients with type 2 AIP is rare (<10%) [10,12]. Therefore, in contrast to type 1 AIP treatment, no upfront maintenance therapy is considered. However, in cases of relapse, a new steroid treatment is effective. Azathioprine (2–2.5 mg/kg/day) may be considered maintenance therapy in relapsing disease, particularly in patients with active IBD [37].

Long-term complications, including pancreatic exocrine insufficiency, the onset of pancreatic calcifications, and malignancy, seem to be uncommon in patients with type 2 AIP [14–16].

Conclusion

Type 2 AIP is a rare disease that is difficult to diagnose because of the lack of serologic markers and, therefore, it is largely underestimated in clinical practice. It clearly differs from type 1 AIP in terms of histology, the clinical profile of patients, and the risk of relapse, despite their similar radiologic appearance and common response to steroids. A strong association with IBD, particularly ulcerative colitis, has been identified, and the concomitant presence of IBD is often necessary to achieve diagnosis of type 2 AIP in clinical practice if a definitive histology is lacking. The clinical onset of IBD generally precedes AIP, but AIP might precede IBD onset in some cases. The incidence of type 2 AIP might be higher in young patients with IBD and acute idiopathic pancreatitis. The clinical outcome of the disease is more favorable, in terms of disease relapse and pancreatic exocrine and endocrine insufficiency, compared to type 1 AIP.

Clinical Diagnostic Criteria for Autoimmune Pancreatitis

Tooru Shimosegawa

South Miyagi Medical Center, Shibata, County, Miyagi, Japan

Historical View of the Diagnostic Criteria for AIP

The Japan Pancreas Society (JPS) was the first in the world to have proposed the diagnostic criteria for AIP in 2002 [1]. Subsequent efforts to improve the prototype produced multiple diagnostic criteria, including the criteria of Asan Medical Center in 2006 [2], the revised criteria of Japan in 2006 [3], and the revised criteria of Asan Medical Center in 2006 [4]. Rapid progress in the understanding of this disease necessitated multiple revisions within a short time, such as atypical cases presenting with focal swelling or tumor-like appearance of the pancreas, besides the typical diffuse enlargement of the pancreas, the discovery of serum IgG4 as a specific biomarker for AIP, and the recognition of AIP as a systemic disease because of the association with various extrapancreatic lesions showing characteristic pathologic findings similar to those observed in the pancreas. Repeated discussions by Japanese and Korean experts over the differences in the criteria proposed by the respective countries led to the postulation of unified criteria in 2008, known as the Asian criteria [5–7]. Meanwhile experts from the Mayo Clinic searched their past database to examine the clinical features of patients with histologically confirmed AIP, and proposed the HISORt criteria in 2006 based on their findings, which consisted of five items, namely, histology (H), pancreatic imaging (I), serology (S), other organ involvement (O), and response to steroids (Rt) [8]. Furthermore, they meticulously compared the characteristics of patients with AIP and those with pancreatic cancer and proposed the revised HISORt criteria in 2009, which categorized the respective diagnostic findings into three groups depending on the strength of the association with AIP or pancreatic cancer [9]. Both the Asian and HISORt criteria were compiled on the assumption that they would diagnose a subtype of AIP that was histologically defined by lymphoplasmacytic sclerosing pancreatitis (LPSP) [10]. However, the first scheme to integrate the two criteria was unsuccessful because of the difference in the diagnostic approaches: while the Japanese and Korean experts considered the unique MPD narrowing judged on ERP as an essential factor for the diagnosis of AIP, the HISORt criteria prioritized the pathologic findings of the pancreas acquired from tissue specimens collected by resection or core biopsy [11,12]. Another newly emerged serious issue was the possibility of another type of AIP that was histologically distinct from LPSP. Idiopathic duct-centric pancreatitis (IDCP)/granulocytic epithelial lesion (GEL) proposed by Western pathologists was characterized by the infiltration of granulocytes into the duct epithelial tissues with destruction of the epithelium, and the clinical features of patients with IDCP/GEL were distinct from those of patients with LPSP [13–15]. It was essential to discuss the true nature of the two distinct subtypes and stipulate diagnostic parameters for each type in order to devise universal diagnostic criteria. Therefore, an international symposium was organized on the sidelines of the joint meeting celebrating the 40th anniversary of the American Pancreatic Association and the JPS in Honolulu in November 2009 to discuss these matters. The final consensus obtained after intense discussions among experts from the East and West was called "the Honolulu consensus," which defined AIP characterized by histologic LPSP as type 1, and that characterized by IDCP/GEL as type 2, and proposed the need for

Companion website: www.wiley.com/go/beger/thepancreas4e

continued efforts to clarify the pathologic condition of the respective type of AIP, especially the autoimmune nature of type 2 [16]. The proposal of the Honolulu consensus enabled the initiation of the process for establishing universal diagnostic criteria for AIP. The Eastern and Western panelists proposed a draft of the ICDC, the final version of which was published after revision in 2011 [17], following discussions at the consensus symposium conducted at the 14th meeting of the International Association of Pancreatology in Fukuoka in July 2010.

International Consensus Diagnostic Criteria for AIP (ICDC)

The ICDC were formulated with the objective of providing a high level of sensitivity and specificity for the identification of AIP, with special focus on its differentiation from pancreatic cancer, after scrutinizing the various diagnostic criteria for AIP formulated and used in various countries and regions [18–21], in addition to the Japanese [1,3,7], Korean [2,4,7], and Mayo Clinic's criteria [8,9]. The ICDC were devised to facilitate accurate diagnosis by various diagnostic approaches, to ensure universal application, even if the preferred diagnostic methods or tests varied according to country or region [17]. The fundamental concept underlying the creation of the ICDC was to combine the merits of the Asian criteria [7] and the HISORt criteria [8,9]: the ICDC was designed to possess high diagnostic ability by virtue of the combinations of various findings other than duct imaging and pancreatic histology, even if ERP and/or pancreatic tissue sampling were not available [22]. Moreover, the ICDC were formulated to diagnose AIP type 1 and 2 separately and clarify the clinicopathologic features of the respective types of AIP prevalent in the world. Even now, the ICDC are the sole diagnostic criteria that can diagnose AIP with differentiation between types 1 and 2.

The ICDC are composed of five cardinal features, namely, parenchymal imaging (P), ductal imaging (D), serology (S), other organ involvement (OOI), and histology of the pancreas (H), whose findings are graded into levels 1 and 2 according to their specificity to AIP, so that the diagnosis of AIP can be made flexibly by collating multiple findings [17]. The response to steroids (diagnostic steroid trial) was provisioned as an option that could be used as a supplementary parameter for diagnosis after thorough examination to eliminate the possibility of biliary and pancreatic cancers (Tables 72.1a and 72.2a). The ICDC consider parenchymal imaging (P), i.e., enlargement of the pancreas, which is easily detectable on CT/MRI, to be an essential finding (akin to the Asian criteria) and classified it in Level 1 (Typical: diffuse enlargement with delayed enhancement) and Level 2 (Indeterminate (including atypical): segmental/focal enlargement with delayed enhancement). Minimum collateral evidence of the other cardinal features is required for the diagnosis of AIP in patients with Level 1 (P). Conversely, the diagnosis of patients with Level 2 (P), in whom the differential diagnosis from pancreatic cancer is important, entails meticulous diagnostic examinations that combine multiple other cardinal findings. The diagnosis of type 1 and 2 AIP can be definitive or probable (Tables 72.1b and 72.2b), and in some cases, the distinction between the subtypes may not be possible (AIP-Not Otherwise Specified) (Table 72.2c). The ICDC reportedly possess the highest sensitivity, specificity, and accuracy for the diagnosis of AIP compared to other diagnostic criteria for AIP reported in the past [22–24].

Table 72.1a Level 1 and level 2 criteria for type 1 AIP Adapted from [17].

Criterion		Level 1	Level 2
P	Parenchymal imaging	Typical: Diffuse enlargment with delayed enhancement (sometimes associated with rim-like enhancement)	Indeterminate (including atypical†): Segmental/focal enlargement with delayed enhancement
D	Ductal imaging (ERP)	Long (>1/3 length of the main pancreatic duct) or multiple strictures without marked upstream dilatation	Segmental/focal narrowing without marked upstream dilatation (duct size, <5 mm)
S	Serology	IgG4, >2× upper limit of normal value	IgG4, 1–2× upper limit of normal value

Table 72.1a (Continued)

Criterion		Level 1	Level 2
OOI	Other organ involvement	a or b	a or b
		a) Histology of extrapancreatic organs Any three of the following: 1) Marked lymphoplasmacytic infiltration with fibrosis and without granulocytic infiltration 2) Storiform fibrosis 3) Obliterative phlebitis 4) Abundant (>10 cells/HPF) IgG4-positive cells	a) Histology of extrapancreatic organs including endoscopic biopsies of bile duct[#] Both of the following: 1) Marked lymphoplasmacytic infiltration without granulocytic infiltration 2) Abundant (>10 cells/HPF) IgG4-positive cells
		b) Typical radiological evidence At least one of the following: 1) Segmental/multiple proximal (hilar/intrahepatic) or proximal and distal bile duct stricture 2) Retroperitoneal fibrosis	b) Physical or radiologic evidence At least one of the following: 1) Symmetrically enlarged salivary/lachrymal glands 2) Radiologic evidence of renal involvement described in association with AIP
H	Histology of the pancreas	LPSP (core biopsy/resection): At least 3 of the following: 1) Periductal lymphoplasmacytic infiltrate without granulocytic infiltration 2) Obliterative phlebitis 3) Storiform fibrosis 4) Abundant (>10 cells/HPF) IgG4-positive cells	LPSP (core biopsy): Any 2 of the following: 1) Periductal lymphoplasmacytic infiltrate without granulocytic infiltration 2) Obliterative phlebitis 3) Storiform fibrosis 4) Abundant (>10 cells/HPF) IgG4-positive cells
Response to steroid (Rt)*		Diagnostic steroid trial Rapid (≦2wk) radiologically demonstrable resolution or marked improvement in pancreatic/extrapancreatic manifestations	

* Diagnostic steroid trial should be conducted carefully by pancreatologists with caveats only after negative workup for cancer including endoscopic ultrasound-guided fine-needle aspiration.
† Atypical: some AIP cases may show low-density mass, pancreatic ductal dilatation, or distal atrophy. Such atypical imaging findings in patients with obstructive jaundice and/or pancreatic mass are highly suggestive of pancreatic cancer. Such patients should be managed as pancreatic cancer unless there is strong collateral evidence for AIP, and a thorough workup for cancer is negative.
# Endoscopic biopsy of duodenal papilla is a useful adjunctive method because ampulla often is involved pathologically in AIP.

Clinical Features of Type 1 and 2 Patients Diagnosed by the ICDC

A multinational study conducted at 23 facilities located in 10 Asian and Western countries recruited 1064 patients with AIP diagnosed using the ICDC (978 patients with type 1 AIP and 86 patients with type 2) and analyzed their clinical features [25]. The results demonstrated that the proportion of type 2 disease was 3.7% in Asian countries, considerably lower than the 12.9% prevalence in European countries and 13.7% in North America; however, it was also evident that AIP type 1 was the dominant manifestation even in Western countries, accounting for over 85% of all patients. The clinical features of patients with AIP types 1 and 2 analyzed in the study coincided with those of previously reported patients with histologic LPSP and IDCP, respectively [26]. Thus, patients diagnosed as AIP type 1 by the ICDC showed a tendency to develop jaundice, especially elderly men, and presented with various extrapancreatic lesions, but only 0.1% had inflammatory bowel disease (IBD). In contrast, patients diagnosed as type 2 were younger than their type 1 counterparts (39.9 years vs. 61.4 years,

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. respectively), without any sex-specific predilection, developed pancreatitis/abdominal pain (64% vs. 27%) more frequently, and nearly half of the patients (48%) developed IBD, but did not present with the various extrapancreatic lesions seen in type 1. Steroids were highly effective for both types, but relapse occurred significantly more frequently in type 1 patients (31%) compared to type 2 patients (9%) [25].

Recent reports from European countries showed similar results with respect to the clinical features of patients with AIP diagnosed by the ICDC with differentiation between types 1 and 2 (see Table 70.1) [27–31]. Studies conducted in the Netherlands [27], Spain [28], Italy [29], Germany [30], and Sweden [31] reported that patients with type 1 AIP tended to be older, predominantly male, and exhibited a greater proportion of serum IgG4 elevation and higher relapse rate compared to those with type 2. Sclerosing cholangitis was the most frequent extrapancreatic lesion in type 1, whereas the incidence of complications such as IBD was significantly higher in type 2. Most patients with types 1 and 2 were treated with steroids, which elicited an excellent response. These findings more or less correspond to those reported by previous multinational studies [25,26], suggesting phenotypic uniformity with AIP types 1 and 2, even in different European countries when the ICDC are used for the diagnosis.

Issues to Be Discussed on the ICDC

Magnetic Resonance Cholangiopancreatography (MRCP)

The ICDC designated the use of ERP-based duct imaging for the diagnosis of AIP [17] because of the insufficient resolution of MRCP for precise judgment of MPD narrowing (especially multiple narrowing), as determined during the compilation of the criteria [7]. Therefore, the perspective of the Japanese and Korean experts who deemed ERP-based identification of MPD narrowing to be mandatory for the diagnosis of AIP was respected and this parameter was incorporated into the ICDC. However, recent advancements, such as the availability of high-resolution MRCP imaging (especially with 3T-weighted MRI), have made it acceptable for the diagnosis of AIP, since the improvement in the MRI apparatus has rendered it almost equivalent to ERP imaging. Japan proposed unique diagnostic criteria for AIP in 2011 (JPS 2011), which were a modification of the ICDC, to render them more convenient and highly specific for the diagnosis of AIP type 1, the exclusively dominant type of AIP in Japan [22,32,33]. Recently, the JPS 2011, which have been used domestically for 7 years were revised partially, and new criteria, i.e., the JPS 2018, were proposed [34]. The JPS 2018 included MRCP imaging for the diagnosis of AIP under the caveat that proper MRI apparatus and suitable conditions would be used for the imaging process, in addition to conventional ERP imaging. The inclusion of MRCP as a diagnostic tool may facilitate the use of the slightly complicated ICDC in daily clinical practice. Therefore, it is important to discuss whether MRCP imaging can be employed for "ductal imaging (D)" of the ICDC in order to promote greater global awareness of AIP.

Endoscopic Ultrasound-Guided Fine-Needle Biopsy (EUS-FNB)

AIP types 1 and 2 are pathologically defined as LPSP and IDCP/GEL, respectively [10,12–14].

The definitive diagnosis of type 1 or 2 AIP can be made by histology alone if Level 1 findings of the "histology of the pancreas (H)" in the ICDC are confirmed. Level 2 findings of (H) also could be extremely helpful for the accurate diagnosis of AIP. The ICDC specify the use of pancreatic tissues obtained by core-biopsy or resection [17], because an adequate amount of tissue samples is required for detailed histologic examination to facilitate precise diagnoses of LPSP and IDCP/GEL. At the time of devising the ICDC, core-biopsy of the pancreas was performed only at a limited number of institutes in the world using the TruCut needle with a long tip [35,36]. However, the long tip and needle stiffness confer several disadvantages, such as difficulty in maneuvering the EUS device when used for the puncture, restriction of the site of the needle insertion only from the stomach (it does not function properly when used in the duodenum apex and the second portion of the duodenum), and restriction of the site of specimen collection to the swollen body of the pancreas [35]. However, several recent studies have suggested that sufficient tissue specimens can be collected by endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) using fine 22-G needles for the diagnosis of LPSP [37,38]. Even more satisfactory results have been reported recently with the use of small-caliber core biopsy needles; the shape and sharpness of the needle tips were refined in order to achieve smooth and safe needle insertion and acquisition of well-shaped samples with preservation of the tissue structure [39–41]. Moreover, the recently published guidance for the diagnosis of AIP by biopsy samples [42] may promote the use of EUS-FNB for the diagnosis of AIP. Therefore, the adequacy of EUS-FNB as a tool for "histology of the pancreas (H)" in the ICDC should be deliberated upon.

Introduction

Autoimmune pancreatitis (AIP) is an enigmatic disease and has stirred up the field of pancreatology and gastroenterology as a whole. After the rediscovery of an autoimmune form of pancreatitis in the 1990s, the pivotal paper described the presence of elevated IgG and IgG4 in this form of pancreatitis (then called "sclerosing" pancreatitis). From histology (see Chapter XX), it became clear that there are two forms of AIP. Just the AIP type 1 was associated with IgG4, both in the serum and tissue. It became further apparent that AIP type 1 is part of a larger syndrome that is now known as IgG-related diseases (IgG-RD). With two types of AIP that may look similar upon imaging (see Chapter XX), but differ in their response to treatment and complications, the need for further serum markers became obvious.

Serum Markers

Generic Markers

The conventional markers of inflammation, namely, erythrocyte sedimentation rate (ESR), leucocytes—white blood cells (WBC), C-reactive protein (CRP), and procalcitonin, are of no use in establishing the diagnosis of AIP. Depending on the character of the respective disease form, stage, and time point, these may or may not be elevated.

Pancreatic Enzymes

Ninety-three years ago, it was stated that "elevated amylase has become a cornerstone in the diagnosis of pancreatitis" [1]. Although the specificity of both serum amylase and lipase for chronic pancreatitis (CP) is acceptable, in the range of 90–95%, their sensitivity is extremely low, oscillating around 10%. Consequently, serum markers can neither be used for establishing the diagnosis of CP nor for the diagnosis of AIP. Serum elastase-1 is useful in acute pancreatitis [2] but has no better performance in CP or AIP [3].

While we could not demonstrate significant differences for absolute values of cationic (PRSS1) and anionic trypsinogen (PRSS2) [4] in AIP, CP, and healthy controls, we found a change in the PRSS1-PRSS2 ratio in healthy individuals (ratio 1 : 3). In AIP (ratio 1 : 2) PRSS2 dominates [4], and in non-AIP CP the ratio was shifted toward PRSS1 (ratio 2 : 1).

If one reflects on how amylase, like any other enzyme, reaches the circulation (serum) [5], its low specificity and sensitivity are not surprising. After massive damage of exocrine pancreatic tissue, that is, leakage through dead cells, serum levels rise significantly; however, this condition is not chronic (autoimmune) pancreatitis, but acute pancreatitis. Other promising markers such as pancreatic stone protein [6] and procarboxypeptidase B [7] have also not fulfilled expectations as sensitive markers for CP and neither are of use in diagnosing AIP.

Taken together, neither a generic marker nor serum levels of pancreatic enzymes can be used to establish the diagnosis of AIP.

Markers of Autoimmunity

Generic markers of autoimmune disease are certain immunoglobulin classes and some other markers. Elevated IgG and especially IgG4 has been the first marker for AIP [8], later found to be related to the type 1 (lymphoplasmacytic sclerosing pancreatitis, LPSP) that

later was determined to be part of the IgG syndrome, immunoglobulin G4-related disease (IgG-RD) [9]. As a result of many studies in AIP, elevated levels of both IgG and/or IgG4 have been determined to be one of the diagnostic criteria for AIP type 1 in the international consortium for diagnostic criteria (ICDC) for AIP [10].

However, serum IgG4 concentrations can be normal in up to 40% of patients with histologically proven IgG4-RD. Several groups have reported a lack of sensitivity and specificity of elevated serum IgG4 levels to establish the diagnosis of IgG4-RD or to distinguish from primary sclerosing cholangitis (PSC) or cholangiocarcinoma [11,12]. Even not good correlation between tissue and serum levels of IgG4 was reported [12]. IgG4 serum levels seem to have diagnostic value when the level is higher than four times the upper level of normal, which is the case in only a minority of patients [11]. This is the reason why IgG4 serum levels should be put in the right context in the diagnostic workup of suspected AIP type 1, and combine with other diagnostic criteria (histology, organ morphology at imaging, search for other organ involvement, and response to glucocorticoid treatment).

Other measures of autoimmunity, i.e., nonspecific markers that can be found are: antinuclear antibodies (ANA = 54–69%), rheumatoid factor (RF = 23–33%), and autoantibodies against smooth muscles (ASMA = 15%) [13,14]. In an attempt to define a serum marker profile, we could not describe a set specifically for AIP [15], even if this was successful for pancreatic cancer [16].

Autoantibodies against specific target tissue-related antigens are the hallmark of any autoimmune disease. Autoantibodies can be divided into two categories: consisting of nonorgan and organ-specific autoantibodies. Shortly after the initial description of IgG4, the first autoantibodies against pancreatic antigens were described in AIP: antibodies against lactoferrin and antibodies against carbonic anhydrase type II, the lead enzyme of the pancreatic duct epithelial lining producing bicarbonate [17]. However, only a small subset of patients seem to be positive [18] (Table 73.1). The third autoantibody described was against SPINK1 [13], a protein known to be disease-facilitating once mutated in some forms of hereditary pancreatitis [19]. These autoantibodies against SPINK1 could be confirmed in an independent patient group by another investigator [4]. Of the autoantibodies described above, only those against carbonic anhydrase type II and lactoferrin are commercially available; however, sensitivity is low and thus their clinical use is limited. Therefore, these autoantibodies cannot be recommended for the diagnosis of AIP [12].

Another autoantibody requires mentioning because it could suggest a link to the possible etiology or causing agent/precipitating event: the ubiquitin-protein ligase E3 component n-recognin 2 (UBR2), is an enzyme highly expressed in acinar cells of the pancreas [20]. There is a certain degree of homology to the plasminogen-binding protein (PBP) of *Helicobacter pylori*—an agent that has been suggested to be linked to AIP for another homology between *Helicobacter pylori cag-A* and human carbonic anhydrase type II in a molecular mimicry fashion [21–23]. However, no confirmatory studies have been performed with URB2. We were also unable to detect *Helicobacter pylori* DNA in pancreatic tissue samples from AIP [24].

Another antibody against the acinar compartment, amylase α2A, was described with good sensitivity and reasonable specificity [25] (Table 73.1); however, this has not been confirmed in larger cohorts.

None of the autoantibodies could be correlated with the expression levels of IgG or IgG4 and when investigated, the autoantibodies were not of the IgG4 class [14]. None of these antibodies are absolutely disease-specific and this is one of the distinct features of AIP compared to other gastrointestinal and liver autoimmune disease characterized by disease-specific autoantibodies such as anti-mitochondrial antibodies (AMA) in PBC and anti-liver kidney microsomal-1 (LKM1) in AIH [14].

Table 73.1 Disease-specific autoantibodies and immunoglobulins in autoimmune pancreatitis.

Antigen	% pos all AIP	AIP 1	AIP 2	Sensitivity	Specificity	% pos in PDAC	References

Preliminary studies have reported promising results for new diagnostic biomarkers for IgG4-RD that might be more accurate than serum IgG4 levels. Next-generation sequencing identified class-switched IgG4+ clones in blood and affected tissue, predominantly in the IgG B cell receptor repertoire [12,26]. The presence of these IgG4+ clones could differentiate active IgG4-RD of the bile ducts and pancreas from other types of hepatopancreatobiliary disease. In a similar way, circulating plasmablasts and CC-chemokine ligand 18 (CCL18) levels seem to have value in the diagnosis of IgG4-RD and in monitoring the disease course [27]. However, confirmation of these preliminary results in larger cohorts is certainly warranted for these markers.

By contrast, blood IgG4 to IgG RNA ratio, previously described as a promising diagnostic marker, lacked specificity for IgG4-RD of the pancreas and bile ducts in a prospective cohort study of patients with suspicion of pancreatobiliary malignancies [12,28]. Of interest, antibodies against prohibitin, annexin A11, and laminin 511-E8 have been found in only a small portion of patients with IgG4-RD [12].

We propose a possible pathomechanism, based on the RNA expression profiling and proteomics data in conjunction with the findings in the blood explaining the occurrence of these antibodies, at least against the acinar antigens (Fig. 73.1). It is based on the fine description of IgG-RD elsewhere [9].

Other Markers

For the diagnosis of (chronic) pancreatitis, especially AIP, some other body fluids could be used. One would be pancreatic juice collected during ERCP or in the duodenum, stimulated after secretin injection. In an attempt to describe markers from pancreatic juice samples, we could not detect any with high-resolution 2D-PAGE [29]. The cytologic analysis will not reveal anything diagnostically relevant for establishing the diagnosis of AIP.

Fecal elastase-1 (FE-1), a marker of pancreatic exocrine insufficiency (PEI), can also be measured. It is a rather crude marker, which if positive (below 200 µg/g) constitutes the diagnosis of PEI and in so doing would

confirm the diagnosis of any sort of chronic pancreatitis. In itself, however, FE-1 is not specific, neither for chronic nor autoimmune pancreatitis.

Conclusion

The only clinically relevant possibilities to diagnose AIP with blood-based assays are serum IgG and IgG4 under consideration of clinical findings. The only commercially available autoantibody assays exist for autoantibodies against lactoferrin, carbonic anhydrase type II, and SPINK1, the latter only in Japan and not in Europe. These three autoantibodies have been shown to be of relevance in several studies. Especially the newer autoantibodies against URB2 and trypsinogens warrant confirmation and the availability of commercial ELISA tests as well as results of the promising studies on next-generation sequencing. So far, attempts to find novel markers have been unsuccessful.

Introduction

Autoimmune pancreatitis (AIP) is a distinct type of chronic pancreatitis that is presumably caused by autoimmune mechanisms. Although several immune markers have been identified for AIP diagnosis, immunoglobulin (Ig) G4 has been established as the most reliable in differentiating AIP from such mimicking conditions as pancreatic cancer as well as in the prediction of relapse during follow-up [1,2]. This chapter will discuss the evidence on measuring immune markers in AIP, with special reference to their usefulness in diagnosis, differentiation from mimickers, and prediction of relapse. AIP has been restricted to type 1 in this chapter since the detailed clinical features of type 2 AIP remain unclear.

Evidence on the Utility of Markers in AIP Diagnosis

In earlier paper electrophoresis assays, most patients with AIP were observed to display a polyclonal band in the rapidly migrating fraction representative of the now characteristic phenomenon of β-γ globulin bridging (Fig. 74.1). Immunoprecipitation trials revealed this finding to be due to high serum concentrations of IgG4 [2]. Moreover, approximately 90% of AIP patients exhibited increased serum IgG4 values, whereas few patients with other diseases, including pancreatic cancer, chronic pancreatitis, primary biliary cholangitis (PBC), primary sclerosing cholangitis, and Sjögren syndrome, showed such elevations (Fig. 74.2) [2]. In contrast, high levels of total IgG and IgE were detected in 70% and 33% of AIP patients, respectively, both of which were also positive in a variety of other conditions. The immune markers antinuclear antibody and rheumatoid factor showed low respective detection sensitivities for AIP of 40% and 30%. Disease-specific autoantibodies, such as anti-Sjögren syndrome A (SSA)/Ro, anti-Sjögren syndrome B (SSB)/La, and anti-mitochondrial antibodies, which have been useful in the diagnosis of Sjögren syndrome and PBC, were also rarely observed in AIP [1,3]. The above results strongly indicated IgG4 as a particularly sensitive and specific biomarker for AIP diagnosis. The efficacy of IgG4 in identifying AIP has since become well recognized worldwide. One meta-analysis of seven representative studies showed an overall sensitivity of 82%, specificity of 95%, diagnostic odds ratio (DOR) of 63.9, and favorable area under the receiver operating characteristic curve (AUROC) value of 0.920 ± 0.073 [4]. Another meta-analysis of 15 studies demonstrated similar overall results for IgG4, with a sensitivity of 74%, specificity of 94%, DOR of 62.91, and AUROC of 0.953 [5]. A recent meta-analysis of 13 studies reported comparable overall results of 72% sensitivity, 93% specificity, 51.37 DOR, and 0.72 AUROC [6], and a nationwide survey on AIP in Japan involving 1449 patients showed a sensitivity of 84.5% [7]. Consequently, serum IgG4 measurement has been adopted as a key item in numerous diagnostic criteria systems for AIP [8,9].

The infiltration of IgG4-bearing plasma cells in affected pancreatic tissue has been established as a histologic hallmark for the pathologic diagnosis of AIP [10]. Additionally, the discovery of extrapancreatic involvement with IgG4-bearing plasma cell infiltration in various tissues has helped identify the new disease concept of IgG4-related disease (IgG4-RD). AIP is now recognized as a pancreatic manifestation of this systemic

disease, for which IgG4 seems to exert a major pathogenic role and accordingly has been recognized as a useful diagnostic marker [1,11,12].

Apart from IgG4, the serum values of several other immunoglobulins also represent novel diagnostic markers of AIP. Taguchi et al. measured the serum levels of IgG, IgA, IgM, and IgG4 in individuals with AIP or other hepatopancreatic diseases and witnessed that IgM and IgA were markedly decreased in patients with untreated AIP, indicating a reciprocal correlation between IgM or IgA and IgG. Thereafter, the ratios of IgG to IgM and IgG to IgA were determined to be significantly higher in AIP than in other diseases, providing a diagnostic sensitivity and specificity for the differentiation of AIP from other hepatopancreatic conditions almost equivalent to those of IgG4 [13]. Those ratios show promise as useful, low-cost markers that require only simple calculations based on routine immunoglobulin examinations. Ikemune et al. have reported that patients with AIP display increased serum k and λ free light chain (FLC) concentrations, summated FLC, and κ/λ ratios, all of which may be useful in diagnosing AIP and monitoring disease activity [14]. Recent studies have also identified increased serum levels of interferon (IFN)-α and interleukin (IL)-33 [15], as well as several causative autoantigens in AIP and IgG4-RD including laminin 511 [16], annexin A11 [17], and galectin-3 [18]. Further research is needed to validate their utility as diagnostic immune markers.

Evidence on the Utility of Markers in Differentiating AIP from Mimicking Conditions

AIP is reportedly characterized by elderly male preponderance, onset with obstructive jaundice, apparent pancreatic swelling in various imaging tests, irregular narrowing of the main pancreatic duct, and stenosis of the lower bile duct [1,3]. As these features mimic those of pancreatic cancer, extensive examination is needed for proper differentiation; in fact, 2–3% of individuals who underwent surgery based on a diagnosis of pancreatic cancer were later revealed to have had AIP [19,20]. At a cutoff value of 135 mg/dL, IgG4 level as a biomarker displayed a sensitivity of 90%, specificity of 98%, and accuracy of 95% in distinguishing between AIP and pancreatic cancer [2]. The efficacy of IgG4 in differentiating AIP from pancreatic cancer has since been supported worldwide. One meta-analysis of seven representative studies showed an overall sensitivity of 82%, specificity of 95%, DOR of 144.6, and favorable AUROC value of 0.914 ± 0.191 [4]. Another meta-analysis of 15 studies showed comparable overall results of 73% sensitivity, 93% specificity, 60.61 DOR, and 0.926 AUC [5], with a third such analysis of 13 studies yielding results of 72% sensitivity, 93% specificity, 51.37 DOR, and 0.72 AUROC [6]. However, mild (i.e., <twofold cutoff value) elevations in serum IgG4 have also been seen in pancreatic cancer [21,22]. It must therefore be emphasized that IgG4 elevation alone does not necessarily rule out the existence of malignancy since AIP complicated with pancreatic cancer has been reported as well [23–25]. Shih et al. revealed that AIP and pancreatic cancer patients have distinct IgG-glycosylation profiling. Using classification and regression tree analysis of IgG galactosylation and sialylation ratios to discriminate AIP from pancreatic cancer, the diagnostic accuracy of the glycan markers was 93.8%, with 94.6% sensitivity and 92.9% specificity [26].

AIP is histologically defined as lymphoplasmacytic sclerosing pancreatitis (LPSP) with abundant lymphoplasmacytic infiltration, storiform fibrosis, and obstructive phlebitis [27]. However, another type of AIP histologically identified as idiopathic duct-centric chronic pancreatitis (IDCP) [28] or AIP with granulocytic epithelial lesion (GEL) [29], which is characterized by granulocytic infiltration in the ductal epithelium has been identified mainly in Europe and America. Although both types of AIP share certain imaging finding similarities, IDCP/AIP with GEL has no known correlation with IgG4 [28,30]. AIP is now classified as type 1 or type 2 based on the pathologic subtypes of LPSP and IDCP/AIP with GEL, respectively [31]. In an international survey, type 2 AIP was observed in 8% of cases, with the proportion of this subtype being remarkably lower in Asian countries (3.7%) than in European (12.9%) and North American (13.7%) populations [32].

Evidence on the Utility of Markers in Predicting Relapse

Although individuals with AIP usually respond well to corticosteroid treatment, relapse is a characteristic feature of AIP that occurs in an estimated 23–31% of patients based on several long-term follow-up studies [7,33,34]. Relapse may be a predisposition factor for pancreatic calcification, which in turn possibly triggers the transition to a chronic pancreatitis state with exocrine and endocrine dysfunction [35,36]. Accordingly, useful biomarkers that predict AIP relapse are needed for the establishment of effective prophylactic measures.

IgG4 seropositivity at diagnosis was found to be a significant independent factor of relapse prediction in AIP patients [37–39]. Other investigations also reported significantly higher AIP relapse rates of approximately sixfold in AIP groups with elevated serum IgG4 levels than in those with normal IgG4 values [40,41].

In the clinical course of a 69-year-old woman with AIP who experienced two relapses, serum elevations of IgG4 and immune complex (IC) preceded the overt appearance of each clinical relapse by several months (Fig. 74.3) [42], indicating that IgG4 and IC could predict relapse and represent disease activity with high sensitivity. Elsewhere, persistently elevated serum IgG4 values were associated with AIP relapse and steroid therapy failure of disease control [33,43,44], and Matsubayashi et al. reported that high serum IgG4 levels were related to severe clinical profiles that included jaundice, large pancreatic lesions, a high frequency of extrapancreatic lesions, and relapse [45].

While steroid therapy is generally effective for AIP, the incidence of relapse within 3 years after the start of treatment is relatively high [46]. Maintenance therapy (MT) for 3 years may decrease the frequency of relapse as compared with simple discontinuation of symptomatic treatment at 26 weeks [47]. Thus, it will be crucial to identify accurate predictors of relapse related to the eventual tapering or discontinuation of steroids. Nakamura et al. found that at least four other organ involvements at diagnosis and IgG of 1400 mg/dL or greater at 3 years of MT were predictive factors of relapse after MT for 3 years [48]. Shimizu et al. revealed that the rate of serum IgG4 decrease after the start of treatment was significantly higher in a nonrelapse group than in a relapse one, suggesting that AIP patients responding to initial steroid therapy with a rapid drop in serum IgG4 were less likely

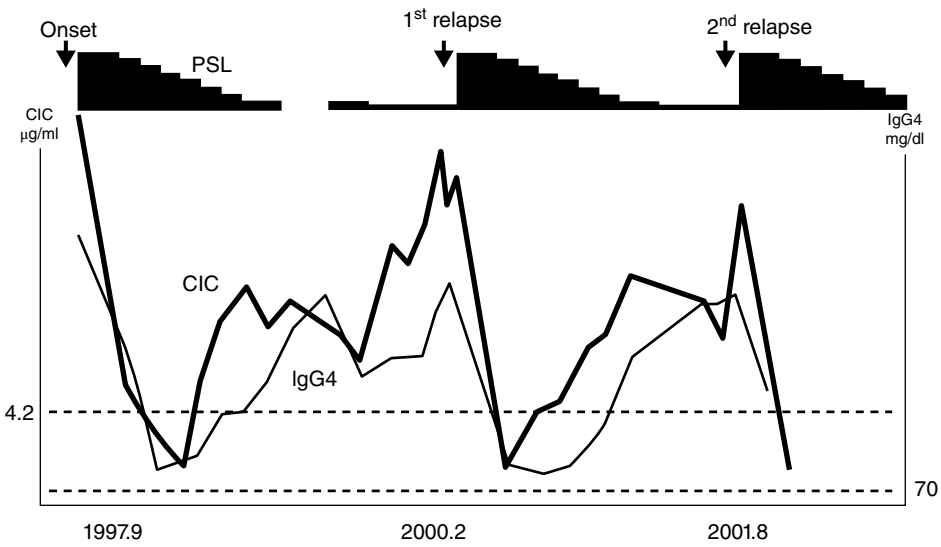

Figure 74.3 Clinical course of a 69-year-old female patient with AIP demonstrating a correlation between two recurrences and preceding IgG4 and IC increases. CIC: circulating immune complex; PSL: prednisolone. *Source:* [42]. With permission of Springer Nature.

to experience a relapse and implicating the rate of IgG4 decrease as a predictor AIP recurrence [49]. In agreement with those findings, the relative rise of serum IgG4 levels after steroid therapy was significantly higher in relapse than in nonrelapse cases [43].

Regarding other immune markers, IC values at treatment onset were significantly higher in a relapse than in a nonrelapse group, indicating possible use as a predictive marker [50]. Additional activity immune markers of AIP include total IgG, complement C3 and C4, soluble interleukin-2 receptor, and β2-microglobulin, all of which may have use in the prediction of AIP relapse [1,3]. Especially since IgG and complement C3 and C4 are low-cost and routinely measured, these parameters represent readily available means of predicting relapse in regular clinical practice and warrant further study.

[3] *Department of Gastroenterology and Hepatology, Kochi Medical School, Kochi University, Nankoku, Kochi, Japan*

Concepts of IgG4-Related Disease

IgG4 related-disease (IgG4-RD) is a fibroinflammatory disorder recognized as a novel clinical entity with multi-organ involvement and unknown origin, associated with abundant infiltration of IgG4-positive cells and fibrosis [1–4] (Fig. 75.1). Involvement of the central nervous system, thyroid, lacrimal glands, salivary glands, breast, lung, liver, bile duct, pancreas, gastrointestinal tract, kidney, prostate, retroperitoneum, arteries, lymph nodes, and skin have been reported [1–3]. Infiltration of IgG4-positive cells, increased serum levels of IgG4, storiform fibrosis, and obliterative phlebitis are characteristic findings of IgG4-RD. The patients with IgG4-RD, either synchronously or metachronously, have diffuse or focal organ enlargement and mass-forming or nodular/thickened lesions in systemic organs [1–4]. IgG4-RD mainly affects middle-aged to elderly men except for IgG4-related dacryoadenitis/sialadenitis, so-called Mikulicz disease. Clinical symptoms vary depending on individual organs and are dramatically relieved by steroid therapy in many cases [1–4]; however, the long-term prognosis still remains unclear. Some patients develop serious complications such as obstructive jaundice due to hepatic, gallbladder, or pancreatic disease; hydronephrosis due to retroperitoneal fibrosis; or respiratory symptoms due to pulmonary disease.

At the 1st International Symposium on IgG4-RD, the nomenclature of individual organ manifestations was proposed (Table 75.1) using "IgG4-related" as a modifier, except for the pancreatic manifestation [3] termed "type 1 autoimmune pancreatitis (IgG4-related pancreatitis)," because it is widely accepted among gastroenterologists and pancreatic surgeons, and helps to discriminate between type 1 and type 2 AIP, which is not a part of the IgG4-RD spectrum. When the pathogenesis of type 2 AIP is clarified, the term "type 1 AIP" might be replaced by "IgG4-related pancreatitis" [3].

Diagnosis of IgG4-RD

The lesions of IgG4-RD are usually detected by imaging (computed tomography [CT], magnetic resonance imaging [MRI], gallium scintigraphy, fluorodeoxyglucose positron emission tomography [FDG-PET]) and blood tests (IgG4 concentration); however, these should be confirmed by histologic findings as much as possible. Organ lesions in IgG4-RD are sometimes misdiagnosed as other mimic disorders in the corresponding organs: lachrymal and salivary gland lesions for Sjögren syndrome, respiratory lesions for sarcoidosis, and sclerosing cholangitis for primary sclerosing cholangitis (PSC) [1–3]. Therefore, it is necessary to differentiate between IgG4-related diseases and mimickers. The patients can be diagnosed by using the Japanese revised comprehensive diagnostic criteria for IgG4-RD (Table 75.2) [5] in 2020 (CDC 2020) or 2019 ACR/EULAR classification criteria (Table 75.3) [6]. The patients who cannot be diagnosed by CDC 2020 may be diagnosed in combination with the CDC 2020 and individual organ-specific diagnostic criteria such as AIP [7], IgG4-related sclerosing cholangitis [8], IgG4-related kidney diseases [9], IgG4-related ophthalmic disease [10], IgG4-related pulmonary disease [11], and IgG4-related periaortitis/periarteritis and retroperitoneal fibrosis [12].

Table 75.1 Preferred nomenclature for individual organ manifestations of IgG4-related disease.

Organ System/Tissue	Preferred Name
Pancreas	Type 1 autoimmune pancreatitis (IgG4-related pancreatitis)
Eye	IgG4-related ophthalmic disease is the general term for the peri-ocular manifestations of this disease. There are several subsets, outlined below.
Lacrimal glands	IgG4-related dacryoadenitis
Orbital soft tissue (orbital inflammatory pseudotumor)	IgG4-related orbital inflammation
Extra-ocular muscle disease	IgG4-related orbital myositis
Orbit with involvement of multiple anatomic structures	IgG4-related pan-orbital inflammation (includes lacrimal gland disease, extra-ocular muscle involvement, and other potential intra-orbital complications)
Salivary glands (parotid and submandibular glands)	IgG4-related sialadenitis or, more specifically, IgG4-related parotitis or IgG4-related submandibular gland disease
Pachymeninges	IgG4-related pachymeningitis
Hypophysis	IgG4-related hypophysitis
Thyroid (Riedel's thyroiditis)	IgG4-related thyroid disease
Aorta	IgG4-related aortitis/peri-aortitis
Arteries	IgG4-related periarteritis
Mediastinum	IgG4-related mediastinitis
Retroperitoneum	IgG4-related retroperitoneal fibrosis
Mesentery	IgG4-related mesenteritis
Skin	IgG4-related skin disease
Lymph node	IgG4-related lymphadenopathy
Bile ducts	IgG4-related sclerosing cholangitis
Gallbladder	IgG4-related cholecystitis

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Table 75.1 (Continued)

Organ System/Tissue	Preferred Name
Liver	IgG4-related hepatopathy (refers to liver involvement that is distinct from biliary tract involvement)
Lung	IgG4-related lung disease
Pleura	IgG4-related pleuritis
Pericardium	IgG4-related pericarditis
Kidney	IgG4-related kidney disease. The specific renal pattern should be termed IgG4-related tubulointerstitial nephritis and membranous glomerulonephritis secondary to IgG4-RD. Involvement of the renal pelvis should be termed IgG4-related renal pyelitis.
Breast	IgG4-related mastitis
Prostate	IgG4-related prostatitis

Table 75.2 The revised 2020 comprehensive diagnostic criteria for IgG4-related disease.

1) clinical and radiological features
   One or more organs show diffuse or localized swelling or a mass or nodule characteristic of IgG4-RD. In single organ involvement, lymph node swelling is omitted.
2) serological diagnosis
   Serum IgG4 levels greater than 135 mg/dl.
3) pathological diagnosis
   Positivity for two of the following three criteria:
   ① Dense lymphocyte and plasma cell infiltration with fibrosis.
   ② Ratio of IgG4-positive plasma cells /IgG-positive cells greater than 40% and the number of IgG4-positive plasma cells greater than 10 per high powered field.
   ③ Typical tissue fibrosis, particularly storiform fibrosis, or obliterative phlebitis.

Diagnosis:
Definite: 1) + 2) + 3)
Probable: 1) + 3)
Possible: 1) + 2)

Source: [5]. With permission of Elsevier.
Explanatory note 1: Combination of organ-specific diagnostic criteria*.
Patients with a possible or probable diagnosis by comprehensive diagnostic criteria who fulfill the organ-specific criteria for IgG4-RD are regarded as being definite for IgG4-RD.
* Diagnostic criteria according to the IgG4-related organ: ① International consensus diagnostic criteria for autoimmune pancreatitis [7], ② IgG4-related lacrimal gland, saliva adenitis diagnostic criteria [8], ③ Diagnostic criteria for IgG4-related kidney disease [9], ④ Clinical diagnostic criteria of IgG4-related sclerosing cholangitis 2012 [10], ⑤Diagnostic criteria for IgG4-related ophthalmic disease [11], ⑥Diagnostic criteria for IgG4-related respiratory disease [12], ⑦ Diagnostic criteria for IgG4-related large periarteritis/periarteritis and retroperitoneal fibrosis [13].
Explanatory note 2: exclusion diagnosis.
1) It is important to acquire tissue samples from each involved organ to distinguish malignant tumors (e.g., cancer, malignant lymphoma) and similar benign conditions (e.g., Sjögren syndrome, primary sclerosing cholangitis, multicentric Castleman's disease, secondary retroperitoneal fibrosis, granulomatosis with polyangiitis, sarcoidosis, eosinophilic granulomatosis with polyangiitis).
2) It is important to exclude an infectious- or inflammation-related disease in patients with high fever, highly elevated CRP and neutrophilia.
Explanatory note 3: pathologic diagnosis.
1) The numbers of IgG4-positive cells are usually more abundant in resected organs and partially enucleated tissue than in tissue samples obtained by needle biopsy or endoscopic biopsy. Thus, it is important to not be too particular about cell number and to provide a precise judgment.
2) Storiform fibrosis is defined as spindle-shaped cells, inflammatory cells and fine collagen fibers forming a flowing arrangement. Obliterative phlebitis is defined as fibrous venous obliteration with inflammatory cells. Both are helpful for a diagnosis of IgG4-RD. ① and ③ without ② can only be applied in a case with poor IgG4 and/or IgG staining.
Explanatory note 4: steroid reactivity.
Steroid trial is not recommended. However, if patients do not respond to initial steroid therapy, the diagnosis should be reconsidered.

Table 75.3 The 2019 American College of Rheumatology/European League Against Rheumatism classification criteria for IgG4-RD.

Step	Categorical assessment or numerical weight
Step 1. Entry criteria	
Characteristic* clinical or radiological involvement of a typical organ (eg, pancreas, salivary glands, bile ducts, orbits, kidney, lung, aorta, retroperitoneum, pachymeninges or thyroid gland (Riedel's thyroiditis)) OR pathological evidence of an inflammatory process accompanied by a lymphoplasmacytic infiltrate of uncertain aetiology in one of these same organs	**Yes**† or No
Step 2. Exclusion criteria: domains and items‡	Yes or **No**§
Clinical	
Fever	
No objective response to glucocorticoids	
Serological	
Leucopenia and thrombocytopenia with no explanation	
Peripheral eosinophilia	
Positive antineutrophil cytoplasmic antibody (specifically against proteinase 3 or myeloperoxidase)	
Positive SSA/Ro or SSB/La antibody	
Positive double-stranded DNA, RNP or Sm antibody	
Other disease-specific autoantibody	
Cryoglobulinemia	
Radiological	
Known radiological findings suspicious for malignancy or infection that have not been sufficiently investigated	
Rapid radiological progression	
Long bone abnormalities consistent with Erdheim-Chester disease	
Splenomegaly	
Pathological	
Cellular infiltrates suggesting malignancy that have not been sufficiently evaluated	
Markers consistent with inflammatory myofibroblastic tumour	
Prominent neutrophilic inflammation	
Necrotizing vasculitis	
Prominent necrosis	
Primarily granulomatous inflammation	
Pathologic features of macrophage/histiocytic disorder	
Known diagnosis of the following:	
Multicentric Castleman's disease	
Crohn's disease or ulcerative colitis (if only pancreatobiliary disease is present)	
Hashimoto thyroiditis (if only the thyroid is affected)	
If case meets entry criteria and does not meet any exclusion criteria, proceed to step 3.	
Step 3. Inclusion criteria: domains and items¶	
Histopathology	
• Uninformative biopsy	0
• Dense lymphocytic infiltrate	+4

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Table 75.3 (Continued)

Step	Categorical assessment or numerical weight
• Dense lymphocytic infiltrate and obliterative phlebitis	+6
• Dense lymphocytic infiltrate and storiform fibrosis with or without obliterative phlebitis	+13
• Immunostaining**	0–16, as follows: Assigned weight is 0 if the IgG4+:IgG+ ratio is 0%–40% or indeterminate and the number of IgG4+ cells/hpf is 0–9.‡‡Assigned weight is 7 if: (1) the IgG4+:IgG+ ratio is ≥41% and the number of IgG4+cells/hpf is 0–9 or indeterminate or (2) the IgG4+:IgG+ ratio is 0–40% or indeterminate and the number of IgG4+ cells/hpf is ≥10 or indeterminate.Assigned weight is 14 if: (1) the IgG4+:IgG+ ratio is 41%–70% and the number of IgG4+ cells/hpf is ≥10 or (2) the IgG4+:IgG+ ratio is ≥71% and the number of IgG4+ cells/hpf is 10–50.Assigned weight is 16 if the IgG4+:IgG+ ratio is ≥71% and the number of IgG4+ cells/hpf is ≥51.
Serum IgG_4 concentration	
• Normal or not checked	0
• >Normal but <2× upper limit of normal	+4
• 2–5× upper limit of normal	+6
• ≥>5× upper limit of normal	+11
Bilateral lacrimal, parotid, sublingual and submandibular glands	
• No set of glands involved	0
• One set of glands involved	+6
• Two or more sets of glands involved	+14
Chest	
• Not checked or neither of the items listed is present	0
• Peribronchovascular and septal thickening	+4
• Paravertebral band-like soft tissue in the thorax	+10
Pancreas and biliary tree	
• Not checked or none of the items listed is present	0
• Diffuse pancreas enlargement (loss of lobulations)	+8
• Diffuse pancreas enlargement and capsule-like rim with decreased enhancement	+11
• Pancreas (either of above) and biliary tree involvement	+19
Kidney	
• Not checked or none of the items listed is present	0
• Hypocomplementemia	+6
• Renal pelvis thickening/soft tissue	+8
• Bilateral renal cortex low-density areas	+10
Retroperitoneum	
• Not checked or neither of the items listed is present	0
• Diffuse thickening of the abdominal aortic wall	+4
• Circumferential or anterolateral soft tissue around the infrarenal aorta or iliac arteries	+8
Step 4: Total inclusion points	
A case meets the classification criteria for IgG4-RD if the entry criteria are met, no exclusion criteria are present, and the total points is ≥20	

(*Continued*)

Table 75.3 (Continued)

* Refers to enlargement or tumor-like mass in an affected organ except in (1) the bile ducts, where narrowing tends to occur, (2) the aorta, where wall thickening or aneurysmal dilatation is typical and (3) the lungs, where thickening of the bronchovascular bundles is common.
† If entry criteria are not fulfilled, the patient cannot be further considered for classification as having IgG4-RD.
‡ Assessment for the presence of exclusion criteria should be individualised depending on a patient's clinical scenario.
§ If exclusion criteria are met, the patient cannot be further considered for classification as having IgG4-RD.
¶ Only the highest weighted item in each domain is scored.
** Biopsies from lymph nodes, mucosal surfaces of the gastrointestinal tract and skin are not acceptable for use in weighting the immunostaining domain.
†† 'Indeterminate' refers to a situation in which the pathologist is unable to clearly quantify the number of positively staining cells within an infiltrate, yet can still ascertain that the number of cells is at least 10/hpf. For a number of reasons, most often pertaining to the quality of the immunostain, pathologists are sometimes unable to count the number of IgG4+ plasma cells with precision yet even so, can be confident in grouping cases into the appropriate immunostaining result category.
hpf, high-power field; IgG4-RD, IgG4-related disease.

Concepts of AIP

AIP is a distinct form of pancreatitis clinically characterized by frequent presentation with obstructive jaundice with or without a pancreatic mass. Recent studies have suggested that AIP is classified as two distinct subtypes, types 1 (IgG4-related pancreatitis) and type 2 with granulocytic epithelial lesion (GEL) [13,14], and the International Consensus Diagnostic Criteria (ICDC) for AIP [7], which enabled the differentiation of type 1 from type 2 AIP and is the most accepted major diagnostic criteria.

Type 1 AIP (IgG4-Related Pancreatitis)

Type 1 AIP accounts for the great majority of cases in Asia, and is frequently associated with obstructive jaundice in elderly males and extrapancreatic manifestations that respond to steroid therapy [1–7]. Clinically, type 1 AIP seems to be the pancreatic manifestation of IgG4-RD, characterized by: (i) mild abdominal symptoms, usually without acute attacks of pancreatitis; (ii) occasional occurrence of obstructive jaundice; (iii) increased serum gammaglobulin, IgG, and/or IgG4 concentrations; (iv) presence of autoantibodies; (v) diffuse, segmental or focal enlargement of the pancreas with a capsule-like low-density rim on dynamic CT/MRI images; (vi) irregular narrowing of the main pancreatic duct on endoscopic retrograde cholangiopancreatography (ERCP) images; (vii) histopathologically, lymphoplasmacytic sclerosing pancreatitis (LPSP): abundant infiltration of lymphocytes and IgG4-positive plasmacytes and fibrosis, and obliterative phlebitis; (viii) occasional association with other organ involvements (Figs. 75.2 and 75.3).

Type 2 AIP

Although type 1 AIP often occurs in older men and is accompanied by a variety of extrapancreatic lesions, type 2 AIP has no gender difference, younger age at onset (often <40 years). The most characteristic feature of type 2 AIP is the GEL [13,14], often with destruction and obliteration of the pancreatic duct (Figs 75.4 and 75.5). Type 2 AIP has swelling of the pancreas, but no or very few IgG4-positive plasma cells. Clinical features show a distinctly different profile, without serum IgG4, IgG elevation, presence of autoantibodies, or other organ involvement, except for inflammatory bowel disease.

Diagnosis of AIP

The patients with type 1 or type 2 AIP often have obstructive jaundice with similar pancreas imaging, but differentiation between these two subtypes and their associated diagnostic criteria has been achieved in the ICDC for AIP [7], which enabled an independent clinical diagnosis for each type. The diagnosis of type 1 AIP by ICDC requires a combination of five primary cardinal features (Tables 75.4 and 75.5): (i) imaging features of (a) pancreatic parenchyma (CT or MRI) and (b) pancreatic duct (ERCP or magnetic resonance cholangiopancreatography [MRCP]); (ii) serology (IgG4); (iii) other organ involvement; (iv) histopathology of the pancreas; and (v) response to steroid therapy. Conversely, the diagnosis of type 2 AIP is made in a combination of four of the primary cardinal features from type 1, excluding serology (Tables 75.6 and 75.7): (i) imaging features of (a) pancreatic parenchyma (CT/MRI) and (b) pancreatic duct (ERCP or MRCP); (ii) ulcerative colitis as other organ involvement; (iii) histopathology of the pancreas; and (iv) response to steroid therapy. Each criterion, except

Table 75.4 Diagnosis of definitive and probable type 1 AIP using ICDC.

Diagnosis	Primary Basis for Diagnosis	Imaging Evidence	Collateral Evidence
Definitive type 1 AIP	Histology	Typical/indeterminate	Histologically confirmed LPSP (level 1 H)
	Imaging	Typical Indeterminate	Any non-D level 1/level 2 Two or more from level 1 (+level 2 D*)
	Response to steroid	Indeterminate	Level 1 S/OOI + Rt or level 1 D + level 2 S/OOI/H + Rt
Probable type 1 AIP		Indeterminate	Level 2 S/OOI/H + Rt

* Level 2 D is counted as level 1 in this setting. *Source:* [7]. With permission of Wolters Kluwer Health, Inc.

Table 75.5 Level 1 and level 2 criteria for type 1 AIP.

	Criterion	Level 1	Level 2
P	Parenchymal imaging	Typical: Diffuse enlargement with delayed enhancement (sometimes associated with rim-like enhancement)	Indeterminate (including atypical†): Segmental/focal enlargement with delayed enhancement
D	Ductal imaging (ERP)	Long (>1/3 length of the main pancreatic duct) or multiple strictures without marked upstream dilatation	Segmental/focal narrowing without marked upstream dilatation (duct size, <5 mm)
S	Serology	IgG4, >2 × upper limit of normal value	IgG4, 1–2 × upper limit of normal value
OOI	Other organ involvement	a or b a) Histology of extrapancreatic organs Any three of the following: 1) Marked lymphoplasmacytic infiltration with fibrosis and without granulocytic infiltration 2) Storiform fibrosis 3) Obliterative phlebitis 4) Abundant (>10 cells HPF) IgG4-positivc cells b) Typical radiological evidence At least one of the following: 1) Segmental/multiple proximal (hilar/intrahepatic) or proximal and distal bile duct stricture 2) Retroperitoneal fibrosis	a or b a) Histology of extrapancreatic organs including endoscopic biopsies of bile duct‡: Both of the following: 1) Marked lymphoplasmacytic infiltration without granulocytic infiltration 2) Abundant (>10 cells/HPF) IgG4-positivc cells b) Physical or radiological evidence At least one of the following: 1) Symmetrically enlarged salivary/lachrymal glands 2) Radiological evidence of renal involvement described in association with AIP
H	Histology of the pancreas	LPSP (core biopsy/resection) At least 3 of the following: 1) Periductal lymphoplasmacytic infiltrate without granulocytic infiltration 2) Obliterative phlebitis 3) Storiform fibrosis 4) Abundant (>10 cells/HPF) IgG4-positive cells	LPSP (core biopsy) Any 2 of the following: 1) Periductal lymphoplasmacytic infiltrate without granulocytic infiltration 2) Obliterative phlebitis 3) Storiform fibrosis 4) Abundant (>10 cells/HPF) IgG4-positive cells
Response to steroid (Rt)*		Diagnostic steroid trial Rapid (≤2 wk) radiologically demonstrable resolution or marked improvement in pancreatic/extrapancreatic manifestations	

* Diagnostic steroid trial should be conducted carefully by pancreatologists with caveats (see text) only after negative workup for cancer including endoscopic ultrasound-guided fine needle aspiration.
† Atypical: Some AIP cases may show low-density mass, pancreatic ductal dilatation, or distal atrophy. Such atypical imaging findings in patients with obstructive jaundice and/or pancreatic mass are highly suggestive of pancreatic cancer. Such patients should be managed as pancreatic cancer unless there is strong collateral evidence for AIP, and a thorough workup for cancer is negative (see algorithm).
‡ Endoscopic biopsy of duodenal papilla is a useful adjunctive method because ampulla often is involved pathologically in AIP.

Table 75.6 Level 1 and level 2 criteria for type 2 AIP.

	Criterion	Level 1	Level 2
P	Parenchymal imaging	Typical: Diffuse enlargement with delayed enhancement (sometimes associated with rim-like enhancement)	Indeterminate (including atypical†): Segmental/focal enlargement with delayed enhancement
D	Ductal imaging (ERP)	Long (>1/3 length of the main pancreatic duct) or multiple strictures without marked upstream dilatation	Segmental/focal narrowing without marked upstream dilatation (duct size, <5 mm)
OOI	Other organ involvement		Clinically diagnosed inflammatory bowel disease
H	Histology of the pancreas (core biopsy/resection)	IDCP: Both of the following: 1) Granulocytic infiltration of duct wall (GEL) with or without granulocytic acinar inflammation 2) Absent or scant (0–10 cells/HPF) IgG4-positive cells	Both of the following: 1) Granulocytic and lymphoplasmacytic acinar infiltrate 2) Absent or scant (0–10 cells/HPF) IgG4-positive cells
Response to steroid (Rt)*		Diagnostic steroid trial Rapid (≤2 wk) radiologically demonstrable resolution or marked improvement in manifestations	

* Diagnostic steroid trial should be conducted carefully by pancreatologists with caveats (see text) only after negative workup for cancer including endoscopic ultrasound-guided fine needle aspiration.
† Atypical: Some AIP cases may show low-density mass, pancreatic ductal dilatation, or distal atrophy. Such atypical imaging findings in patients with obstructive jaundice and/or pancreatic mass are highly suggestive of pancreatic cancer. Such patients should be managed as pancreatic cancer unless there is strong collateral evidence for AIP, and a thorough workup for cancer is negative (see algorithm).

for steroid responsiveness, is classified as either level 1 or level 2 collateral criteria.

Patients with obstructive jaundice and a diffusely enlarged pancreas (especially with a capsule-like rim) without pancreatic ductal dilatation/cutoff or low density pancreatic masses on CT/MRI are highly likely to have AIP. However, subjects with typical findings of pancreatic cancer (e.g., low-density mass on contrast-enhanced CT, pancreatic ductal dilatation/cutoff with or without pancreatic atrophy) should be considered as having pancreatic cancer. Subjects without features typical of AIP or pancreatic cancer should first be investigated for pancreatic cancer. AIP should be considered only after negative workup of malignancy. Response to steroids can confirm a strong suspicion of AIP; however, steroid trial as a means to diagnose AIP is to be used sparingly and should not be used as a substitute for a thorough search for an etiology.

Treatment

Although some studies of the treatment for IgG4-RD have been reported [15,16], a comprehensive management of IgG4-RD has not yet been established. As clinical features of the patients with IgG4-RD depend on characteristics of involved organs, the current consensus for treatment of type 1 AIP [17] as a representative lesion of IgG4-RD is described (Fig. 75.6).

Induction for Remission

Steroid treatment can successfully induce remission in most of the patients with type 1 AIP (~90%) [16–24]. The Japanese guidelines [19] and international consensus [17] have recommended steroids as the first-line agent in all active and symptomatic patients with untreated AIP, who have obstructive jaundice or abdominal and/or back pain due to pancreatic or other organ involvements, unless patients have any contraindications or high risk for steroid use. They have also recommended steroid

treatment even in asymptomatic patients with persistent pancreatic mass on imaging, or those with associated IgG4-related sclerosing cholangitis (IgG4-SC) who have persistent liver test abnormalities [17]. In those with contraindications to steroid treatment, rituximab can induce remission as a single agent [17,21]. Except for rituximab, however, other steroid-sparing agents such as thiopurines are poorly effective as a single agent for induction of remission [21]. Before an initial steroid therapy, management of blood glucose in diabetic patients or biliary drainage in patients with obstructive jaundice are recommended [23], because biliary drainage can prevent biliary infection, and brushing or bile juice cytology can differentiate IgG4-SC from biliary malignancy. In some cases of mild jaundice without signs of infection, however, steroid treatment alone can be performed safely without biliary stenting [22].

Relapse and Second-Line Treatment

According to the international or Japanese multicenter study [23], 30–50% of the subjects with type 1 AIP experienced relapse. Most of the risk factors for relapse remain poorly understood and require further study. A history of relapse seems to be a strong risk factor for future relapse. Although an international study [18] could not confirm, the Japanese national retrospective [23,24] studies have suggested that diffuse pancreatic enlargement type, and persistently high, low decreased rate or re-elevation of serum IgG4 levels after steroid therapy, may be predictors of AIP relapse. Association with IgG4-related SC, especially the proximal type of IgG4-SC seems to be a risk factor for relapse. In addition to serum IgG4 levels, circulating immune complexes have been reported as useful early predictors of relapse [19].

Although the usefulness of steroid as an initial treatment is agreed upon, there is no "gold standard" for treatment in relapse cases. The international consensus recommend readministration or dose-up of steroid or steroid-sparing agents such as immune-suppressive agents or rituximab [17].

Maintenance Treatment

Although there is no high-level evidence regarding maintenance therapy, certain patients benefit from maintenance therapy following a successful course of induction therapy [17,19]. Whereas some patients do not relapse following withdrawal of steroids after remission is achieved, some patients relapse during steroid taper or require relatively high-dose maintenance therapy. Therefore, to determine the indications for maintenance therapy, it is important to evaluate disease activity during induction therapy.

Maintenance therapy may consist of low-dose glucocorticoids or any of the steroid-sparing agents.

Retrospective studies from Asian countries, mainly Japan [19], have suggested that steroid maintenance monotherapy may prevent relapse after remission. In addition to retrospective studies, a recent prospective Japanese multicenter study has shown that steroid maintenance therapy provides beneficial outcomes after remission [25].

In cases of low disease activity such as involvement in the pancreas alone with segmental/focal lesion without any OOI and complete radiologic remission with normalized IgG/IgG4 in rapid response to steroid treatment, steroids can be tapered off within 3 months followed by no steroid maintenance [17]. Conversely, maintenance therapy using a low dose of steroid, immune-modulators, or rituximab is recommended in patients with type 1 AIP showing diffuse enlargement of the pancreas, delayed radiologic remission or persistently high serum IgG4 (>2 × UNL) after treatment, or more than two OOI (≥2) or association with proximal IgG4-SC before treatment [17].

Recent Advances in the Pathogenic Mechanisms of IgG4-RD

Although it is unclear whether the pathogenic mechanism is the same among individual organs or not, recent studies have suggested possible multipathogenic factors in the development of AIP similar to other immunogenic diseases. Based on genetic factors, disease-specific or related antigens, abnormal innate and adaptive immunity may be involved [26] (Fig. 75.7).

Immunogenic Backgrounds

Although immunogenic backgrounds are unknown in IgG4-RD, the susceptibility to AIP in Japanese patients, most of whom exhibit IgG4-RD, may be associated with the class II antigen haplotype of the major histocompatibility complex (HLA-DRB1*0405-DQB1*0401) [27,28], polymorphism of nuclear factor-κB, *Fc-receptor-like* (*FCRL*) *3* genes expressed on B cells [29], and *FCGR2B* gene encoding Fc-gamma receptor [28,30]. An inhibitory molecule, *cytotoxic T lymphocyte antigen-4* (*CTLA-4*; *CD152*), expressed on the activated memory T cells or CD4+CD25+ regulatory T cells (Treg), was independently reported as a susceptibility factor [31].

Innate Immunity

Recently, abnormal innate immunity has been demonstrated in some patients with IgG4-RD [32–34]. Activation of NOD-2 and Toll-like receptor (TLR) ligands on monocytes or basophils from patients with IgG4-related AIP enhances IgG4 responses via B-cell activating factor (BAFF) and IL-13, although the specific pathogens still remain unclear [32,33]. Moreover, abundant infiltration of TLR-7 positive M2-macrophages was observed in the pancreatic tissues from type 1 AIP cases [34]. In animal models, activation of TLR3 (polyinosinic:polycytidylic acid) or TLR4 (LPS) can induce immune-mediated cholangitis, pancreatitis, and sialadenitis similar to human IgG4-RD [35,36]. Recently, possible roles of basophils, which are activated via TLR signaling, may be involved in the development of type 1 AIP [37].

Possible Roles of IgG4 in IgG4-RD

Although the association of IgE-mediated allergy and IgG4 antibodies is well known, IgG4 characteristics are still poorly understood. IgG4 is involved in an immune process referred to as "Fab-arm exchange," which is a swapping of a heavy chain and attached light chain (half-molecule) with a heavy-light chain pair from another molecule. This usually results in asymmetric antibodies with two different antigen-combining sites [38]. While these modified antibodies are hetero-bivalent, they behave as monovalent antibodies. Another aspect of IgG4 is that it mimics IgG rheumatoid factor (RF) activity by interacting with IgG, namely through Fc-mediated aggregation [39]. IgG4 seems to be associated with a pathogenic effect in a few situations. In pemphigus, recognition of skin autoantigens (desmogleins) by IgG4 is at the origin of the disease process [40]. The most recent study of structural determinants of human IgG4-Fc using crystallization suggested that Fc–Fc interactions are compatible with intact IgG4 molecules and may provide a model for the formation of aggregates of IgG4 that can cause disease pathology in the absence of antigen [41].

Another recent study of the regulation of IgG4 showed that IgG4-related diseases may reflect an excessive production of anti-inflammatory cytokines such as IL-10, which triggers an overwhelming expansion of IgG4-producing plasma cells [26]. Increased peripheral inducible-memory Treg are positively correlated with serum levels of IgG4 [26]. In addition, prominent infiltration of Treg upregulated IL-10 in livers of patients with IgG4-SC. These findings suggest that IgG4 does not act as a pathogenic factor, nor is it an anti-inflammatory factor in IgG4-RD. Further studies are necessary to clarify the precise role of IgG4 in IgG4-RD.

The Complement System

Patients in active stages of AIP occasionally show decreased complement (C3, C4) with elevated circulating immune complex, as well as elevated serum levels of IgG4 and the IgG4 subclass of immune complexes [42]. However, a previous study showed that the classical pathway of complement activation through IgG1 may be involved in the development of AIP, as opposed to mannose-binding lectin or alternative pathways through IgG4 [42].

Autoantibodies and Candidates of Target Antigens

Although some patients with IgG4-RD have nonspecific antibodies such as an anti-nuclear antibody (ANA), this is rare. From the view of IgG4 function, it remains unclear whether IgG4-RD is an autoimmune or an allergic disease. Although disease-specific targets are unknown, the occasional coexistence of OOI leads us to consider that there may be common target antigens in the involved organs, especially in the pancreas, which exhibit a high coincidence. Among candidate antigens previously reported, lactoferrin (LF), carbonic anhydrase (CA)-II, CA-IV, pancreatic secretory trypsin inhibitor (PSTI) are distributed in the pancreas, salivary glands, biliary duct, lungs, and renal tubules, among others. Immunization with CA-II or LF-induced systemic lesions such as pancreatitis, sialadenitis, cholangitis, or interstitial nephritis in mice models is similar to human IgG4-RD [26]. Amylase alpha-2A, heat shock 10kDa protein 1 (HSP10) and *Helicobacter pylori* are also disease-associated antigen candidates [26].

Recently, four novel candidates of target antigens related with connective tissues in some of the patients with type 1 AIP have been reported; prohibitin [43], annexin A11 [44], laminin 511-E8 [45], and galectin-3 [46,47]. However, autoantibodies against these four antigens are found in only a small portion of the patients with IgG4-RD.

Role of B Cells

In addition to steroid and immune-modulators, the B-cell depletion by rituximab, which reduces only IgG4, but not IgG1, IgG2, or IgG3, is useful in the therapeutic strategy in IgG4-RD [26]. A recent study showed expansion of IgG4+ B-cell receptor (BCR) clones in blood and tissue from patients with active IgG4-cholangiopathy, and disappearance of the clones with corticosteroid treatment. A recent study showed that increased $CD19^{+}CD24^{high}CD38^{high}$ Breg may suppress the disease activity of type 1 AIP, whereas the decreased $CD19^{+}CD24^{high}CD27^{+}$ Breg might be involved in the development of type 1 AIP [26].

Th1 and Th2 Immune Balance

CD4+ T-cells differentiate from naïve T-cells (Th0) into Th1, Th2, Th17, and regulatory T (Treg) cells. In the livers of IgG4-SC patients, a Th2-type immune reaction is predominant over the Th1 responses [26]. Recent studies suggested that IL-33 [48], IL-35 [49], and miRNA-21 [50], promote Th2 immune responses, which may be involved in the progression of the disease process, especially through the maturation and proliferation of local B cells and plasmacytes. Moreover, IL-33

and TNFα may be an additional biomarker monitoring disease activity of type 1 AIP other than serum levels of IgG4 [26].

Regulatory T Cells

Forkhead box P3 (FOXP3) plays as the master regulator in the development of CD4+CD25+ regulatory T cells (Treg). Treg are classified as a naturally occurring CD4+CD25+ Treg (nTreg) that originates in the thymus, while adaptive Treg (aTreg) are induced in the periphery by different antigens [26]. In type 1 AIP, circulatory naïve (CD45RA+) Treg are significantly decreased in the peripheral blood, whereas memory (CD45RA-)-Treg are significantly increased [26]. In addition, prominent infiltration of Treg with upregulation of IL-10 is observed in the liver of type 1 AIP and IgG4-SC patients. These findings suggest that increased memory-Treg in the periphery and local tissues may be an inhibitory immune response against inflammation, although decreased naïve Treg may be pathogenic.

Conclusion

Recent advances support the concept of IgG4-RD, a unique clinical entity, as a systemic disease, and the classification of two distinctive subtypes of AIP. Type 1 AIP is proposed as a pancreatic manifestation of IgG4-RD and type 2 AIP is associated with GEL and inflammatory bowel disease. In the pathogenesis of AIP, multipathogenic factors include genetic backgrounds and disease-specific antigens. The role of IgG4 must be clarified in the near future.

Introduction

The disease concept of autoimmune pancreatitis (AIP) was proposed in 1995 by Yoshida et al.[1], and subsequently this condition has been recognized as the pancreatic manifestation of IgG4-related disease (IgG4-RD) [2]. After several revisions of the concept, AIP is currently recognized as being classified into two distinct types [3,4]. AIP is subclassified according to the International Consensus of Diagnostic Criteria (ICDC) for autoimmune pancreatitis as either type 1 (IgG4-related) or type 2 (granulocytic epithelial lesions; GEL). Both types of AIP present with pancreatic swelling or mass formation often leading to obstructive jaundice. These features are similar to pancreatic cancer on the basis of the clinical and radiologic findings alone.

Histopathologic feature of type 1 (IgG4-related) AIP, termed lymphoplasmacytic sclerosing pancreatitis, is characterized by abundant infiltration of lymphocytic and IgG4-positive plasma cells, obliterative phlebitis, and fibrosis [3,5,6]. Type 2 AIP is characterized by GEL [5,8], histopathologically termed as idiopathic duct-centric chronic pancreatitis (IDCP) [7] and appears to be more common in Western countries than in Asian countries, whereas type 1 AIP accounts for the majority of cases in the world.

This chapter outlines pancreatic imaging based on current diagnostic criteria because of a particularly important role of these techniques in the diagnosis of AIP. Abdominal ultrasound (US), computed tomography (CT), and magnetic resonance (MR) imaging are useful in the morphologic diagnosis of the pancreatic parenchyma. Magnetic resonance cholangiopancreatography (MRCP) and endoscopic retrograde pancreatography (ERP) are useful in the morphologic diagnosis of the pancreatic duct. In addition, positron emission tomography (PET) may be useful in evaluating the response to steroid therapy as well as extrapancreatic involvements. ERP has long been considered essential in Japan for potential AIP cases marked by localized pancreatic swelling [1]. However, in the ICDC and Japanese diagnostic criteria of 2011 it is stated that a possible diagnosis of AIP can be made without ERP if a fine-needle aspiration under endoscopic ultrasonography (EUS) excludes malignancy, and the patient responds to steroid treatment.

Pancreatic Parenchyma Imaging

Diffuse swelling of the pancreas corresponding to a sausage-like appearance is highly characteristic for AIP. This feature can be demonstrated by US, CT, or MRI. However, localized (segmental or focal) swelling in AIP requires differentiation from pancreatic cancer. Concerning the definition of pancreatic swelling many investigators use the Haaga criteria (pancreatic head: ≥1 vertebral body, pancreatic body and tail ≥2/3 of a vertebral body define a pancreatic swelling and correspond roughly to a head of ≥3 cm and a body and tail of ≥2 cm) [12]. As the pancreas may be atrophic in the elderly a strict definition is difficult to achieve, but these criteria make it possible to recognize pancreatic swelling also in cases with shrinkage of the pancreas due to steroid treatment. Although "diffuse" and "localized" are not strictly defined, the ERP findings in the majority of cases with chronic pancreatitis are consistent with the Cambridge classification (2/3<diffuse, 1/3<segmental<2/3, focal<1/3) [13].

Abdominal Ultrasonography (US) [5,11]

The typical US appearance of the pancreas in AIP shows a diffusely swollen organ that resembles a sausage. The swollen portion is hypoechoic with scattered hyperechoic spots. In cases with localized swelling, the differential diagnosis between pancreatic cancer and mass-forming pancreatitis is problematic. Dilatation of the main pancreatic duct is frequently not detected by US, but delineation of the main pancreatic duct within the mass—known as the "duct penetration sign"—is helpful in differentiating AIP from pancreatic cancer [14]. However, the findings of only mild ductal dilatation or multiple hypoechoic masses within the pancreatic parenchyma make a differentiation between AIP and metastatic pancreatic tumors or lymphoma difficult.

Endoscopic Ultrasonography [5,11]

In AIP, typical pancreas EUS findings show a relatively diffuse homogeneous hypoechoic pattern and linear or reticular (tortoiseshell pattern) hyperechoic inclusions in the parenchyma along with a hypoechoic band in the periphery. Compared with chronic pancreatitis, EUS in AIP typically reveals a homogeneous hypoechoic pattern in the pancreatic parenchyma, rarely showing the characteristics of chronic pancreatitis (e.g., heterogeneous texture, lobule-shaped margin, and hyperechoic ductal margin). EUS of localized masses in AIP also display hypoechoic patterns that mimic those of pancreatic cancer. Linear or reticular (tortoiseshell pattern) hyperechoic inclusions and duct penetration are useful signs for distinguishing AIP from pancreatic cancer. Contrast-enhanced EUS sometimes provides useful findings for the differentiation of AIP from pancreatic cancer. EUS with fine-needle aspiration (EUS-FNA) has diagnostic utility not only for discounting pancreatic cancer, but also for diagnosing AIP.

Abdominal CT Imaging [5,11]

The CT features are pancreatic swelling with a straightened margin of the pancreas, a pattern of delayed contrast enhancement on dynamic CT, and a capsule-like rim surrounding the pancreas (Fig. 76.1) [15–17]. Most AIP patients are elderly and therefore tend to have some atrophy of the pancreas before the onset of AIP. This can obscure the presence of pancreatic swelling in the early stages of the disease. Conversely, there are also cases in which pancreatic swelling can be judged to have been present at onset based on a decrease in the size of the pancreas following steroid therapy. Other cases are characterized by atypical findings of mild diffuse swelling of the pancreas alone, and/or partial dilatation of the MPD, cystic lesions, or, in rare cases, calcification of the pancreatic parenchyma.

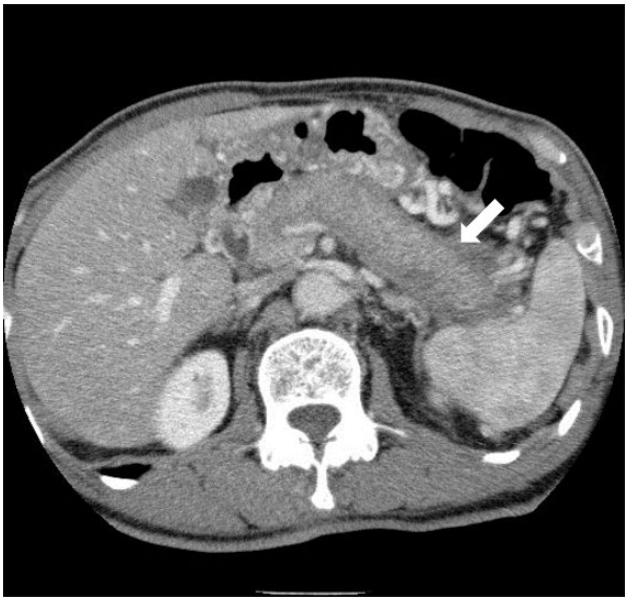

Figure 76.1 Abdominal CT images of autoimmune pancreatitis (diffuse swelling). It shows pancreatic swelling with delayed enhancement (sausage-like) and capsule-like low density rim (arrow).

Pancreatic Swelling and Delayed Enhancement

Delayed enhancement is characteristic on the portal phase of dynamic CT, but the specific findings vary according to disease stage and activity. The enhancement effect can be altered by the degree of fibrosis. If the extent of fibrosis is only mild, the amount of enhancement may be difficult to distinguish from normal pancreas. Thus, the absence of delayed enhancement does not exclude AIP in the early stages of the condition, when extensive fibrosis is unlikely. Speckled/dotted enhancement on the pancreatic phase of dynamic contrast-enhanced CT (DCE-CT) and homogeneous delayed enhancement on the delayed phase of DCE-CT are characteristic features of AIP and are useful for differentiation from pancreatic cancer.

Capsule-Like Low-Density Rim

The finding of a low-density, capsule-like rim around the pancreas is less common than delayed enhancement, but such a finding has a high specificity for AIP [15]. The capsule-like rim is thought to reflect fibrosis at the edge of the lesion, corresponding to the delayed pattern of enhancement observed on dynamic CT. A capsule-like rim is extremely helpful in differentiating AIP from pancreatic cancer. The absence of such a rim, however, by no

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. means excludes AIP. Pancreas imaging alone cannot distinguish type 1 from type 2 AIP due to the similarity of their morphologic appearance.

Abdominal MR Imaging [5,11]

Pancreatic Swelling and T1/T2-Weighted Pancreatic Parenchyma Findings

Hypointensity on T1-weighted MR images and delayed enhancement on the portal phase of dynamic MRI are characteristic of AIP in addition to diffuse swelling. Because the normal pancreas is hyperintense relative to the liver on T1-weighted images, any relative hypointensity detected must be considered abnormal. However, hypointensity on MR is also found in both pancreatic cancer and chronic pancreatitis from other causes, and therefore does not distinguish AIP among these entities. In AIP patients, a duct-penetrating sign is occasionally seen on T2-weighted imaging or MRCP, which is almost never observed in pancreatic cancer. Similar to CT, differentiation of the normal pancreas from cases of only mildly fibrotic AIP is challenging. Conversely, severe fibrosis can be associated with only slight hypointensity on T2-weighted images, because of the limited inflammation present at that point. Similar to DCE-CT images, speckled/dotted enhancement on the pancreatic phase of dynamic contrast-enhanced MRI and homogeneous delayed enhancement on the delayed phase of MRI are characteristic features of AIP and are useful for differentiation from pancreatic cancer.

Capsule-Like Rim

Both a capsule-like rim and a delayed enhancement pattern can be detected by MRI. Both of these findings reflect fibrosis and are highly characteristic for AIP. The capsule-like rim is visualized as a hypointense region on T2-weighted images. Dynamic MRI is the most effective means of demonstrating delayed enhancement.

Nuclear Medicine Examinations

Gallium citrate (Ga-67) scintigraphy and fluorine-18 fluorodeoxyglucose positron emission tomography (FDG-PET) [5,11].

Patients with AIP display an accumulation of gallium citrate (Ga-67) and FDG in pancreatic and extrapancreatic lesions, which disappear shortly after steroid treatment. The characteristic accumulation patterns and kinetics of Ga-67 and FDG following steroids can be used for AIP diagnosis. Ga-67 and FDG accumulate in pancreatic lesions, making the differentiation from lymphoma difficult. Ga-67 and FDG accumulation is not limited to pancreatic lesions alone, but is also found at sites of extrapancreatic involvement, notably in the hilar lymph nodes of the chest, the lacrimal glands, and the salivary glands, which is useful for differentiation from pancreatic cancer. Such lesions frequently disappear rapidly after glucocorticoid administration [18–20]. However, the expense of these examinations further limits their clinical utility and has so far prevented them from entering routine practice.

Pancreatic Duct Imaging

ERCP Findings [5,11]

A characteristic irregular narrowing of the main pancreatic duct (MPD) constitutes strong evidence in favor of the diagnosis of AIP (Fig. 76.2a) [11]. Irregular narrowing of the MPD refers to a situation in which the pancreatic duct diameter is thinner than usual and irregular. These lesions tend to affect greater lengths of the duct than do occlusive or stenotic lesions. In typical cases, irregular narrowing accounts for more than one-third of the entire pancreatic duct length (~5 cm). Even in localized lesions marked dilatation of the main pancreatic duct upstream to the stenotic portion is frequently not observed. In cases with a short irregular narrowing pancreatic duct (roughly <3 cm), the differentiation from pancreatic cancer is difficult. Side branches arising from the narrow area of the MPD and skip lesions are useful signs in the differentiation from pancreatic cancer [5,15]. In the earlier diagnostic criteria for AIP put forth in Japan the finding of characteristic irregular narrowing within the MPD was considered to be an essential piece of diagnostic evidence [5,11]. In cases with focal irregular narrowing, the need to differentiate AIP from pancreatic cancer must be kept in mind. In AIP bile duct stenosis is found in about 80% of cases. Bile duct stenosis is most common in the inferior bile duct (Fig. 76.2b, c), but may also develop in the extrahepatic and intrahepatic bile ducts. Although a locally enlarged AIP lesion is sometimes difficult to differentiate from pancreatic cancer, AIP enlargement is improved by corticosteroid therapy.

MRCP Findings [5,11]

When evaluating patients with possible AIP and other disorders that mimic it, delineation of the morphologic features of the MPD by ERP or another direct visualization method is essential. At present, MRCP does not delineate the pancreatic duct with sufficient accuracy for reliable diagnosis of AIP or the precise evaluation of irregular narrowing in the MPD. Its ability to demonstrate noncontinuity of the duct is helpful in making the diagnosis of AIP (Fig. 76.3), although the specificity of this finding, in itself, is imperfect. However, 3-dimensional

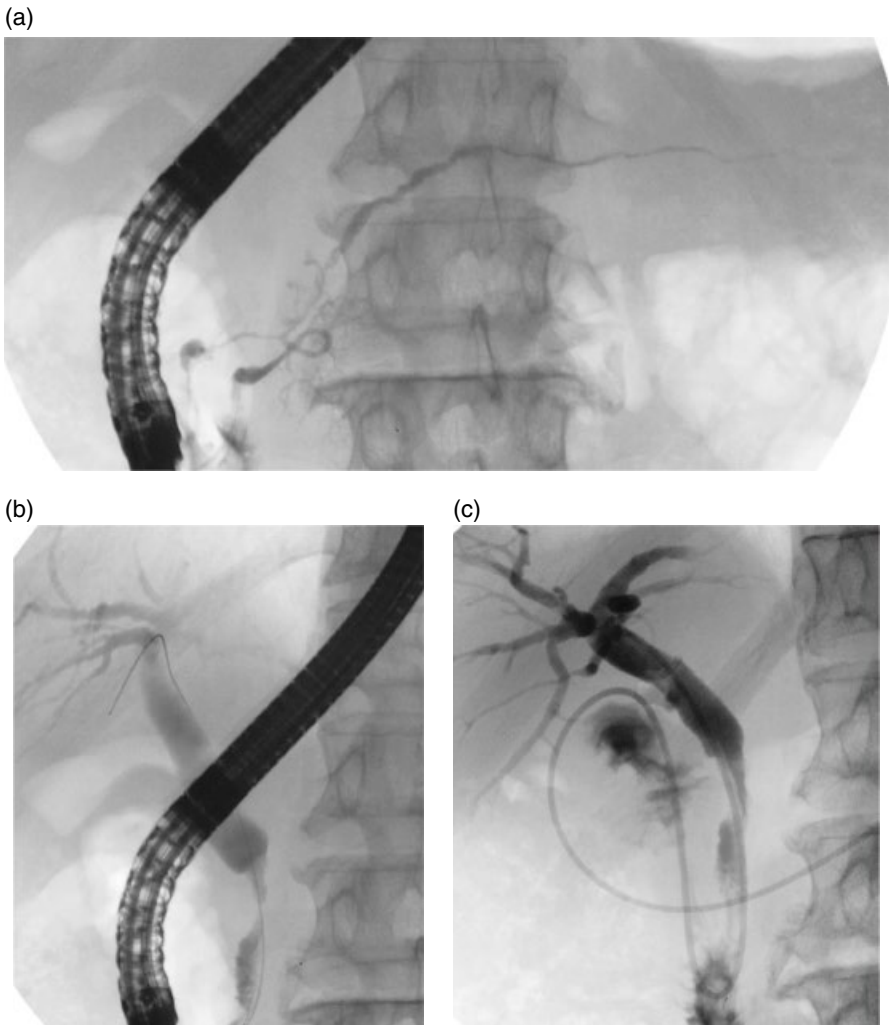

Figure 76.2 ERCP images of autoimmune pancreatitis. ERP (a) shows irregular narrowing in the pancreatic head and tail. Side branches arising from the stenotic portion of the main pancreatic duct (MPD) in the pancreas head can be observed. Before steroid treatment, ERC (b) shows stenosis of the terminal common bile duct and improvement of stenotic change after steroids (c).

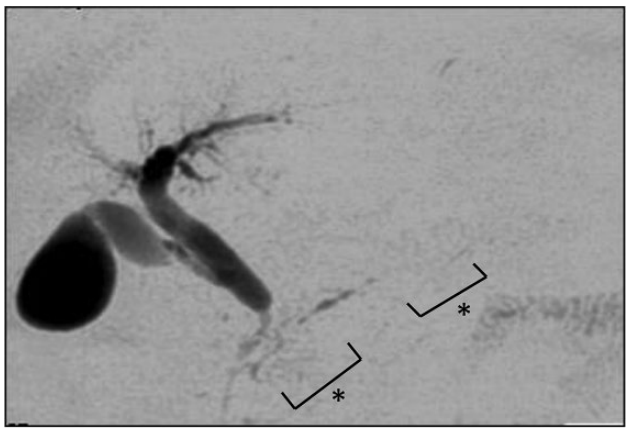

Figure 76.3 MRCP findings of autoimmune pancreatitis. MRCP usually fails to identify the correct presence of irregular narrowing of the MPD. In this case, MRCP shows the segmented MPD (skip lesions), suggesting the possibility of autoimmune pancreatitis (*).

MRCP can now detail the MPD within a normal pancreas and failure to identify the main duct suggests the presence of irregular narrowing. With the recently introduced 3.0 Tesla MR imagers, further enhancement of the image quality of MRCP is anticipated and MRCP may have a greater role to play in the assessment of the response of AIP to therapy and in follow-up observations.

Medical Management of Autoimmune Pancreatitis

Shounak Majumder[1] *and Suresh T. Chari*[2]

Introduction

In 1995, Yoshida et al. coined the term autoimmune pancreatitis (AIP) to describe a condition reminiscent of autoimmune hepatitis because it was corticosteroid-responsive and associated with elevated levels of autoantibodies and gamma globulins [1]. Earlier, Kawaguchi had described its histopathologic features and called it lymphoplasmacytic sclerosing pancreatitis (LPSP) [2]. Subsequently, this entity was shown to be the pancreatic manifestation of a multiorgan disorder called IgG4-related disease (IgG4-RD).

A different disease entity was seen to share some histopathologic and clinical features with LPSP, and was termed idiopathic duct-centric chronic pancreatitis (IDCP) [3]. The term AIP eventually came to be used for both diseases with LPSP termed type 1 AIP and IDCP as type 2 AIP. Here the term AIP will be used to indicate LPSP and the term IDCP to describe this distinct entity.

Management of Autoimmune Pancreatitis: An Overview

AIP is managed medically; surgical intervention, usually pancreatic resection or biliary bypass for "unresectable" disease, occurs when the condition is mistaken for pancreaticobiliary cancer. Like other autoimmune disorders, treatment of AIP includes induction of remission, treatment of relapse, and maintenance of remission. The cornerstone of medical management of AIP is the use of corticosteroids to target the inflammatory response in the affected organ. This provides symptom relief, often dramatic, which in some instances can be helpful for confirming the diagnosis. Although the early use of corticosteroids may delay progression to fibrosis, pancreatic parenchymal fibroatrophic changes that accompany the initial presentation of the disease are usually permanent. Steroid-sparing agents are mostly used for long-term maintenance of remission or in steroid-intolerant patients.

Definitions

The consistent use of well-defined terms to describe treatment goals is an important component of the treatment algorithm of AIP. AIP is a fibroinflammatory disease and treatment targets the inflammatory component; the accompanying fibrosis may permanently alter organ structure and function. Currently, there are no therapies that specifically prevent or halt fibrosis.

"Remission" indicates the complete resolution of the inflammatory component of the disease with or without restitution of normal structure and function. The rapid and complete resolution of symptoms such as jaundice or abdominal pain after initiation of corticosteroids has diagnostic utility; persistent symptoms on high-dose steroids indicate an alternate diagnosis. Even with remission organs affected may never return to normal morphology and function due to fibrosis-related damage. Biochemical abnormalities in liver tests and pancreatic enzymes typically resolve completely with disease remission. Confirmation of histologic remission after treatment, although ideal, is not feasible and is almost never

needed in clinical practice. Normalization of serum IgG4 levels is not a reliable treatment target and does not correlate with disease remission.

"Recrudescence" is the worsening of disease or "flare" during treatment when the disease is still not in remission. This may happen in the setting of corticosteroid dose reduction or premature withdrawal.

"Relapse" refers to disease recurrence after complete remission has been achieved. This could be in the form of recurrent clinical, radiologic, or biochemical features of disease that often mimic the initial presentation. AIP being part of a multiorgan disease (IgG4-RD), relapse may occur in the organ being treated or in another, previously unaffected, organ. Abdominal pain as a standalone symptom is rarely a manifestation of relapse. Similarly, isolated "serologic relapse," that is, elevation of IgG4 without biochemical or radiologic change, is not indicative of disease relapse and should not be treated.

Management of Initial Presentation

Induction of Remission

Corticosteroids are the mainstay of initial treatment. High-dose induction therapy with 30–40 mg/day of prednisone or equivalent-dose corticosteroid is typically administered for 4 weeks. Clinical and radiologic response is assessed at the end of 4 weeks of high-dose therapy and in patients demonstrating remission or significant interval improvement in target organ inflammation, this is followed by a gradual corticosteroid taper using a decremental dose of 5 mg per week. Subsequent need for therapy is determined by treatment response. For patients with no previous history of AIP who have limited disease burden that rapidly resolves, steroid therapy is typically tapered to discontinuation at this stage.

Maintenance of Remission

In patients who achieve complete remission with induction therapy, there is considerable debate regarding the continued use of low-dose corticosteroid treatment for maintenance of remission. In a meta-analysis that included 36 studies, the relapse rate in AIP patients treated successfully with corticosteroid induction was noted to be 20% at 1 year and 53% at 4 years [4]. Several Asian centers favor the long-term continuation of low-dose corticosteroid therapy for several years and even indefinitely, whereas most centers in Europe and North America recommend weaning to discontinuation over 8–10 weeks after the initial 4 weeks of high-dose treatment. However, in a large study of 459 subjects with AIP from Japan who received maintenance corticosteroid treatment nearly one fourth relapsed (23%, 63/273) [5]. Though this was lower compared to patients in whom corticosteroids were discontinued after achieving remission (34%, 35/104; $P = 0.048$), the authors do not provide treatment alternatives for those who did relapse on steroids [5]. In a more recent randomized controlled trial, after induction of remission with corticosteroids, patients were randomized to either maintenance therapy with prednisolone at 5–7.5 mg/day for 3 years or steroid withdrawal at 26 weeks. The 3-year relapse rate was significantly lower in the maintenance therapy group than that in the cessation group (23% vs. 58%) [6].

An alternative approach to steroid maintenance therapy is the use of immunomodulators as a steroid-sparing agent. The choice of immunomodulator does not impact treatment outcomes with 6-mercaptopurine, mycophenolate mofetil, and azathioprine all having similar efficacy. Intolerance to one agent can be managed by substituting one of the other agents. The optimal dose and duration of treatment is not well defined. However, for azathioprine, higher doses similar to those used in the management of inflammatory bowel disease (2.0–2.5 mg/kg), have a greater likelihood of preventing subsequent relapses compared to lower doses (1 mg/kg) [7]. Although azathioprine may be effective in maintaining remission in patients with AIP it is important to recognize that up to 20% patients will relapse while on treatment with azathioprine [8].

Follow-Up and Management of Disease-Related Sequelae

Exocrine Insufficiency

Steatorrhea is uncommon in patients with AIP. A study using a diagnostic cutoff of FE-1 < 200 µgm/gm reported an abnormal test result in more than 80% of patients with AIP [9]. A recently published meta-analysis estimated the pooled prevalence of exocrine insufficiency to be 45% at diagnosis; however, there appears to be wide variability of estimates among studies. This remains discordant with our clinical observations that clinically overt exocrine insufficiency is uncommon. It is unlikely that FE-1 values at a cutoff <200 µgm/gm accurately reflect the true prevalence of exocrine pancreatic insufficiency in patients with AIP. Significant pancreatic parenchymal atrophy is seen in up to 25% patients after corticosteroid therapy and may contribute to the development of exocrine dysfunction over time [10]. The use of pancreatic enzyme replacement therapy should be

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

limited to patients with clinical evidence of fat malabsorption.

Endocrine Insufficiency

Risk factors for the development of new-onset diabetes in patients with AIP include extensive pancreatic parenchymal atrophy, long duration of disease, advanced age, smoking, and alcohol consumption. Periodic monitoring of glycemic status should be considered for early detection and timely intervention, especially in patients with the aforementioned risk factors and in those with frequent high-dose or long-term corticosteroid exposure.

Risk of Pancreatic Malignancy

There is conflicting evidence regarding the risk of pancreatic cancer in patients with AIP. Although some studies have shown increased risk, others have failed to establish an association. The risk of cancer appears to be highest in the first year after diagnosis of AIP [11]. In a study of 107 AIP patients with a median follow-up of 74 months, none of the study subjects developed pancreatic cancer [12]. Interestingly, eight patients developed a nonpancreatic malignancy and the cancer risk in this study cohort was comparable to an age- and gender-matched reference population. The concomitant diagnosis of AIP and pancreatic cancer has also been reported [13]. Although this phenomenon is exceedingly rare, it highlights the importance of a detailed diagnostic workup to exclude pancreaticobiliary malignancy before embarking on an AIP treatment protocol. Also, malignancy should be considered in the differential diagnosis of patients who do not respond to corticosteroid induction since primary nonresponse to steroid therapy is extremely unusual. Both synchronous and metachronous pancreatic cancer has been reported in AIP, the latter appears to be more common and typically arises from the part of the gland affected by AIP.

Management of Medication Side-Effects

Corticosteroids

Hyperglycemia, sleep disturbance, and altered mood are the most frequent and clinically relevant treatment-related complications linked to high-dose corticosteroid therapy. For those with a preexisting mood disorder, careful assessment of mental health status, and if necessary, medication dose adjustment should be considered prior to initiation of treatment. A baseline fasting plasma glucose should be obtained in all patients and those with a preexisting diagnosis of diabetes mellitus closely monitored to modify steroid and insulin dosing. Less commonly encountered serious side-effects of high-dose steroids include avascular necrosis, osteoporosis, hypertension, and worsening heart failure.

Immunomodulators

Unfortunately, in most reported series up to a quarter of patients treated with immunomodulators have experienced treatment-limiting side-effects [7]. The commonly encountered adverse effects that result in drug discontinuation include nausea, liver enzyme elevation, drug rash, myelosuppression, and bacteremia. A switch to a different immunomodulator is tolerated in about half of these patients.

Management of Idiopathic Duct-Centric Pancreatitis (Type 2 AIP)

IDCP is exquisitely steroid-responsive. The dose and duration of induction treatment with corticosteroids is similar to AIP. Clinical response is often dramatic and relapses are infrequent. A Mayo Clinic study of 31 subjects with a definitive diagnosis of IDCP reported a relapse rate of 10.6% at 12 months [14]. Initial presentation with acute pancreatitis predicted a lower relapse-free survival. Relapses almost always respond to retreatment with corticosteroids. In view of the relatively low relapse rate, maintenance therapy with steroids or immunomodulators is currently not recommended. Long-term disease-related sequelae such as pancreatic duct stones, pancreatobiliary malignancy also appear to be less common compared to type 1 AIP.

Conclusion

In patients with a confirmed diagnosis of AIP the initial medical management is straightforward. Treatment of relapses and disease that does not respond or incompletely responds to high-dose corticosteroids requires a thoughtful approach with the judicious use of immunomodulators and B-cell depletion therapy (Fig. 77.1). Although, RTX appears to be the agent of choice for the treatment of patients with refractory disease, the optimum dosing regimen and duration of treatment continues to evolve and needs further study. Novel biomarkers that allow disease activity surveillance and predict relapse may facilitate more accurately tailored treatment regimens in the future.

Management of Intractable Autoimmune Pancreatitis

Shounak Majumder[1] *and Suresh T. Chari*[2]

[1] *Division of Gastroenterology and Hepatology, Mayo Clinic College of Medicine, Rochester, MN, USA*
[2] *Department of Gastroenterology, Hepatology and Nutrition, University of Texas MD Anderson Cancer Center, Houston, TX, USA*

Introduction

Autoimmune pancreatitis (type 1) is exquisitely steroid sensitive, both initially and in relapse. However, in a small subset of patients it may be hard to induce remission or maintain remission. This group has been termed "intractable or refractory," though it does not necessarily mean complete lack of responsiveness to steroids, which is rare.

Definition of Intractable or Refractory Disease

Intractable or refractory AIP can be defined as disease that is hard-to-treat due to inability or inefficacy of first-line treatments for induction and/or maintenance of disease remission.

Subsets of Refractory AIP

These have not been systematically characterized or studied. Based on our experience there are five possible scenarios (A–E): (A) steroid intolerance; (B) prompt relapse after or during withdrawal of steroid induction treatment or relapse on low-dose steroid maintenance; (C) immunomodulator intolerance or inefficacy; (D) prompt relapse following withdrawal of maintenance treatment; or (E) relapse on rituximab (RTX) maintenance or RTX intolerant. Such scenarios are reported [1–9], but systematic studies of individual scenarios are limited.

Management of Refractory Disease (Fig. 78.1)

A) **Steroid intolerance**

While steroid intolerance is not very common, therapeutic options are fairly limited in these patients (scenario A). RTX, a chimeric monoclonal antibody against CD20 antigen on B cells, is the only currently known agent other than corticosteroids that can induce remission on its own. Generally reserved for treatment of relapsing disease, it can be used as a first-line agent in select clinical scenarios when steroids are contraindicated or poorly tolerated. The most used induction regimen for RTX is two doses (1 gm each) 2 weeks apart. There is limited data and no consensus on the use of RTX as first-line treatment for AIP. In a Mayo Clinic series, complete remission was achieved in three out of three patients who were corticosteroid-naïve and were treated with RTX as the first-line agent [4]. However, experience from treatment of other manifestations of IgG4-RD and more recent published experience from our center suggests that RTX can be used as first-line and sole agent for induction and maintenance of remission, if necessary [2,6]. The safety and efficacy of RTX in IgG4-related disease has recently been reported [5].

B) **Prompt recurrence on or during withdrawal of standard steroid induction treatment or disease requires high doses of steroids to induce remission**

Some patients will relapse soon after steroid taper despite successful and complete improvement while on steroids, while others may be unable to be weaned off high-dose

corticosteroids following induction therapy due to disease recrudescence. Options for such patients include reintroducing high-dose steroids and adding immunomodulators like azathioprine or mycophenolate, overlapping the two for 4–6 weeks before tapering steroids again. The other option is to consider RTX as noted in scenario A. These two approaches of using maintenance therapy at index presentation of disease may be considered for patients at the highest risk of early relapse. This includes patients with proximal biliary tract disease, diffuse enlargement of the pancreas, elevated baseline IgG4, IgE, peripheral eosinophilia, and possibly those with persistent elevation of IgG4 at the end of induction therapy [9]. It is to be noted that immunomodulators do not induce remission; hence, if the disease is still active when steroids are withdrawn or there is early relapse, there is a high likelihood of disease recrudescence, despite use of immunomodulators (see scenario C below).

C) **Inability to use or inefficacy of immunomodulators**

A subset of patients started on immunomodulators may be intolerant to the drug [4]. There are others who do not go into remission when transitioned from steroids to immunomodulators. Some may achieve and stay in remission on immunomodulators, but relapse months later while still on treatment. Relapse may occur in the same organ for which treatment was initiated or in another previously unaffected organ. While all such scenarios have been reported in AIP [4], there is no systematic study of management of such patients.

In those with drug intolerance, one could potentially switch to another class of agents (e.g., mycophenolate for azathioprine or 6-MP or vice versa). If not intolerant to drug, one strategy is to reintroduce steroids, and increase immunomodulator dose (up to 2 mg/kg for azathioprine or 1 gm b.i.d. for mycophenolate). After reinduction of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. remission, steroids may be tapered while continuing the immunomodulator. In both these strategies it can take months to know if a successful and sustained remission has been achieved, all the while being on double immunosuppression (steroid + immunomodulator) and attendant risks.

As we have noted above managing immunomodulators in the difficult-to-treat patient can be cumbersome and time-consuming. Due to this, we have not used this strategy. We have instead elected to use RTX as the sole immune-suppressive agent [4] as described in scenario A. This strategy has worked consistently and successfully [4,6].

D) **Prompt recurrence of disease after withdrawal of maintenance treatment**

While we have chosen, in general, to stop immunesuppression after 2 years, a small subset of patients seem to require indefinite immunosuppression to keep disease in remission. This can happen with all approaches to maintenance therapy (low-dose steroids, steroid-sparing immunomodulators or biologic agents [RTX]). The management in these patients is similar to that in scenario B: using steroids for reinduction while reintroducing the immunosuppression used previously for maintenance vs. using RTX alone with a short course of steroids if patient has an urgent indication, like obstructive jaundice. If using RTX, such patient will require reinduction with two doses of 1000 mg 2 weeks apart.

E) **Relapse on rituximab maintenance or rituximab intolerance**

In our experience relapse on RTX maintenance is a very rare event. However, some patients may develop RTX intolerance due to allergic reactions and recurrent infections or may not be an ideal candidate for RTX maintenance therapy due to concomitant medical comorbidities. Possible treatment options for these patients include low-dose prednisone if able to tolerate it or immunomodulators, if not previously tried. This further highlights the need for clinical trials to identify novel treatment options for refractory AIP while recognizing the challenges associated with drug development in a small subset of an uncommon disease.

Frequency and Dose of RTX for Maintenance Therapy

For maintenance therapy a single dose of 1000 mg of RTX has been used [6]. Lower doses have not been systematically studied. We tend to use it every 4–6 months for a total duration of 2 years of maintenance therapy. Although relapses may occur after discontinuation of RTX maintenance, it is relatively infrequent (approximately 10% in our limited experience) and currently it remains unclear if the risks of long-term immunosuppression outweigh the benefits of maintaining remission. In patients with refractory AIP and a high disease burden associated with prior relapses such as hospitalization, sepsis, need for urgent endoscopic biliary decompression, or significant end-organ dysfunction, maintenance therapy beyond 2 years may be considered as an individualized approach. The Mayo experience suggests that median time to relapse is 14 months [6]. Based on these data, it is possible that longer intervals (9 months or 12 months) may suffice. However, the number of patients treated with various intervals is too small to draw firm conclusions.

Use of Biosimilars as a Substitute for RTX

A biosimilar is a biologic product that is highly similar to a licensed biologic ("originator"). Biosimilar and originator have no clinically meaningful differences in safety, purity, or potency. A number of RTX biosimilars are being tested in Europe and the United States and some have been approved for clinical use. In a recent study an RTX biosimilar Truxima was shown to be a safe and effective alternative to RTX in IgG4-related disease [10].

Side-Effects of RTX

Rituximab treatment is fairly well tolerated, and infections are the most common side-effect. All patients should be screened for hepatitis B virus prior to initiation of therapy since reactivation hepatitis B can potentially result in fulminant liver failure [11]. Common infusion-related adverse reactions include flu-like symptoms, pruritus, transient hypotension, and bronchospasm. Serious infusion reactions are rare, but near-fatal infusion reactions have been reported [12]. Other rare serious reactions that would necessitate discontinuation of therapy include toxic epidermal necrolysis and progressive multifocal leukoencephalopathy.

Long-Term Outcome After Treatment of Autoimmune Pancreatitis

Luca Frulloni and Nicolò de Pretis

Department of Medicine, Gastroenterology Unit, Pancreas Center, University of Verona, Verona, Italy

Introduction

Autoimmune pancreatitis (AIP) is a clinical entity that is well described in clinical and imaging findings at the onset of the disease [1]. The early phase is well defined, particularly the outcome after first steroid treatment, which represents a diagnostic criterion. However, the long-term outcome of patients suffering from AIP is still largely unknown. Many aspects are not yet fully clarified, particularly the need for and efficacy of treatment with nonsteroidal immunosuppressants (azathioprine) or biologics (rituximab [RTX]) in preventing disease relapse and progression toward chronic pancreatitis in terms of loss of pancreatic function (exocrine and endocrine insufficiency), onset of pancreatic calcifications, and the risk for pancreatic cancer.

Since the term "autoimmune pancreatitis" was introduced in 1995 [2] and the disease was recognized later as a clinical entity, when a steroid treatment has become the norm, the long-term outcome of the disease has been modified by the use of steroids, nonsteroidal immunosuppressant drugs, and/or RTX. Therefore, while the natural history of the disease remains obscure, what can be observed nowadays is the long-term outcome of AIP after therapy. An unanswered question is the fate of patients suffering from AIP before 1995 and more appropriate maintenance treatment. We know that some of them underwent surgery because of the suspicion of pancreatic cancer. To answer this question may lead to a better understanding of the natural history of AIP.

Disease Relapse After Steroids and Treatment

Relapse of AIP may be symptomatic, evident on imaging, serologic, and/or histologic [3]. However, an AIP relapse may be clinically asymptomatic and detectable only on imaging [4]. The site of the relapse is mainly in the pancreas, but may involve extrapancreatic organs (kidney, salivary glands, biliary tree, and retroperitoneum) [4–7]. Positron emission tomography/computed tomography has been proposed as a useful imaging modality both for staging and for evaluation of treatment response in IgG4-related diseases, which include type 1 AIP [8–10]. Relapse rates reported in the literature include symptomatic and asymptomatic patients with both pancreatic and extrapancreatic involvement without distinction.

After a first course of steroids, disease relapse has been reported in between 13% and 64% of cases (Table 79.1) [6,11–25]. Disease relapse does not differ between patients who underwent surgery compared to those treated conservatively (Table 79.2) [6,12–16,18,26]. Furthermore, relapse rates are significantly higher and more frequently observed in AIP type 1 compared to type 2 [6,21,27]. De Pretis et al. [28] reported a 15% relapse rate of AIP-NOS (not otherwise specified), lower than in type 1 (34%) and similar to that of type 2 AIP (6%) [21]. Furthermore, the authors observed a 25% probability to switch from a diagnosis of type NOS to type 2 AIP at 5 years, and never to AIP type 1.

High levels of serum IgG4 [6,7,12,15,27,29–31], intrahepatic biliary involvement [6,29,32], and other organ involvement [7], have all been identified as risk factors for relapse. These factors were all strictly correlated with type 1 AIP, which may therefore be considered as a more aggressive disease.

The treatment of choice for disease relapse is a new course of steroids (prednisolone) to induce remission [33]. This therapeutic approach is widely accepted, even if it is based only on cohort studies. The dosage of prednisolone is the same as that proposed after the diagnosis of AIP (prednisolone, 30–40 mg/day or a weight-adjusted dose range from 0.5 to 1 mg/kg of body weight

per day), which can be varied according to disease activity. After the induction of remission in relapsing AIP a maintenance regimen has been suggested. Long-term maintenance therapy with low-dose steroids (prednisolone, 5–10 mg/day) is used in Asian countries but is still debated elsewhere. Steroid-sparing agents, in particular azathioprine (2–2.5 mg/kg/day), have been proposed for long-term treatment of relapsing AIP [34–36], even in the absence of controlled trials, but again their use is still under debate. However, experts recommend an add-on therapy with steroid-sparing agents for IgG4-related disease [37], to which AIP type 1 belongs.

Rituximab (RTX), an anti-CD20 antibody inducing B-cell depletion, seems to be effective in inducing specific serum IgG4 reductions and for better disease control in IgG4-RD, even in steroid refractory cases [38]. RTX probably interferes with the immunologic processes underlying IgG4-RD, but the exact mechanism is still unknown. Since AIP type 1 is considered a manifestation of IgG4-RD, the use of RTX has been suggested for this subtype of AIP [37,39]. Some preliminary cohort studies seem to confirm the efficacy of RTX in AIP type 1 [40–42]. There is still no consensus regarding the dosage and the RTX schedule. A rheumatologic (intravenous infusions at a dosage of 375 mg/m^2 body surface area at time points 0 and 15 days, repeated after 6 months) rather than a hematologic schedule (intravenous 375 mg/m^2 body surface area four times at weekly

intervals, then repeated infusions every 2–3 months up to 24 months) can be suggested, but randomized trials are needed to better understand the most appropriate protocol for AIP patients.

Loss of Pancreatic Function and Evolution Toward Chronic Pancreatitis

The long-term outcome of AIP patients is described in only few studies and limited to the first 10 years after clinical onset. The key points about the natural history of AIP are the deterioration of exocrine and endocrine function, the onset of pancreatic calcifications, and, more generally, the evolution toward "ordinary" chronic pancreatitis.

Exocrine pancreatic function is already reduced at clinical onset of the disease (Table 79.3) [5,12,14,23–25,43–45] and its improvement has been observed in a significant proportion, but not all, patients after steroids [43,46]. The exocrine pancreatic function evaluated by secretin-cerulein test is reduced at clinical onset of the disease in nearly all AIP patients, involving particularly enzyme production more than bicarbonate secretion [47]. After steroids, studies have shown that exocrine pancreatic insufficiency evaluated by PABA test [43] or fecal elastase-1 [46] improved, but severe pancreatic insufficiency remained in 33–50% of cases. However, pancreatic exocrine insufficiency remains present in a large portion of AIP patients (80%) in the long-term follow-up after steroids [45]. Therefore, evaluation of pancreatic function in AIP is recommended to identify patients who may benefit from pancreatic enzyme replacement therapy.

Similar data have been published for endocrine pancreatic function (Table 79.3) [5,12,14,43–46], and diabetes is quite common in AIP. Steroid-induced diabetes is frequently observed at clinical onset of the disease, particularly in older patients [46,48].

The results of long-term follow-up suggest that some patients with AIP could develop pancreatic calcifications, generally after several disease relapses [30,31,49]. Steroid treatment seems to prevent progression toward chronic pancreatitis [50].

Loss of pancreatic exocrine and endocrine function, onset of calcifications, and atrophy of the pancreatic gland seem to suggest that AIP can transform into "ordinary" chronic pancreatitis. This hypothesis, even if not completely supported by clinical data and imaging findings, could explain why AIP was not identified in the past and may have been confused with chronic calcifying pancreatitis in its advanced stage.

This hypothesis also implies that imaging is only typical for AIP in the early phase of the disease and the diagnosis can be more easily achieved. In the more advanced stage, the radiologic features are less suggestive for AIP, and it is highly probable that the diagnosis of AIP will be missed.

Figure 79.1 shows a diagram of the postulated natural history of AIP.

Risk for Pancreatic and Extrapancreatic Cancer

A risk for pancreatic cancer in AIP has been reported [30,44,51–59], as for other chronic inflammatory gastrointestinal diseases, but studies are limited to case reports or small series. The risk for pancreatic adenocarcinoma is highest in the early phase of the

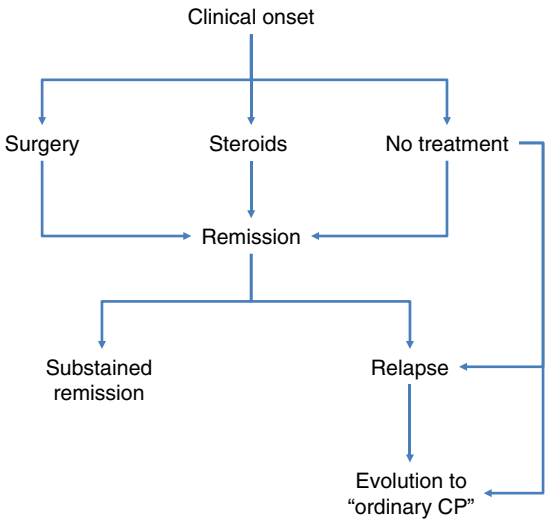

Figure 79.1 Natural history of autoimmune pancreatitis based on evidence in the literature.

disease, probably because the imaging features of AIP and pancreatic cancer can overlap, and lower in a more advanced phase.

The clinical implication is therefore to exclude cancer at the clinical onset of the disease, and to monitor AIP patients by imaging techniques during follow-up, not only to diagnose the disease relapse, often asymptomatic, but also for an early diagnosis of cancer.

The incidence of extrapancreatic cancer within 5 years from diagnosis of AIP is high, ranging from 6.6% to 13.9% [6,60–62]. The increased risk for extrapancreatic malignancy has been reported for AIP type 1, but not for AIP type 2, which may be related to the patient's age more than the AIP subtype. It is still debated whether this incidence is increased compared to the general population. In any case, physicians should be aware that 10% of patients could develop a cancer after diagnosis of AIP and, therefore, the use of immunosuppressant drugs and biologics should be carefully evaluated.

Epidemiology of Cystic Neoplasms of the Pancreas

Shounak Majumder[1] *and Suresh T. Chari*[2]

[1] *Division of Gastroenterology and Hepatology, Mayo Clinic College of Medicine, Rochester, MN, USA*
[2] *Department of Gastroenterology, Hepatology and Nutrition, University of Texas MD Anderson Cancer Center, Houston, TX, USA*

Introduction

Pancreatic cystic lesions (PCL) can be histopathologically classified as nonneoplastic or neoplastic. Nonneoplastic cysts do not have any malignant potential and include pseudocyst, lymphoepithelial cyst, retention cyst, hydatid cyst, and enteric duplication cyst. Neoplastic cysts, termed pancreatic cystic neoplasms (PCN) have potential to develop malignancy or are malignant at diagnosis. PCN are further classified as serous cystic neoplasm (SCN), mucinous cystic neoplasm (MCN), intraductal papillary mucinous neoplasm (IPMN) (including branch-duct and main-duct IPMN), solid-pseudopapillary neoplasm (SPN), and cystic change in an otherwise solid tumor (e.g., ductal adenocarcinoma or neuroendocrine tumor). The risk of malignancy in these cysts varies from <1% in SCN to >60% in main-duct IPMN [1–3].

PCL are increasingly being identified in asymptomatic patients on routine imaging studies [4]. While a neoplastic nature of PCL <5 mm in size is not always certain, larger, surgically resected cysts are mostly neoplastic, with IPMN being the most common PCN [5]. However, the vast majority of PCL are not resected [6] and therefore, PCL >10 mm in size are presumed to be PCN and are managed accordingly. Studies based purely on imaging diagnosis of pancreatic cysts can provide information on incidence and prevalence of PCL in the general population [7,8]. However, these studies lack confirmatory histopathologic diagnosis and are based on referral populations in the healthcare setting. In contrast, although surgical series cannot be used to determine the true incidence and prevalence in the general population, they have the advantage of providing histopathologic confirmation [5,6]. We use the term PCL in reference to data from imaging studies and PCN for data from surgical series. Although, some studies on PCL do make presumptive histopathologic diagnoses based on imaging and, when available, cyst fluid characteristics; however, preoperative diagnosis may be incorrect in nearly one-third of PCL when correlated with surgical histopathology [9].

Pancreatic Cyst Lesions

Incidence

There is limited information on the incidence of PCL in the general population. A study from Olmsted County, MN showed the prevalence of PCL suspected to be IPMN was 4.35 per 100,000 persons in 2005 [8] (Fig. 80.1). The age- and sex-adjusted incidence had risen 14-fold compared to 1985, when it was 0.31 per 100,000 (Fig. 80.1). This growing incidence was felt to be secondary to diagnostic scrutiny rather than a true increase in incidence over time. In this study, other non-IPMN pancreatic cysts such as SCN were excluded.

Prevalence

In hospital-based studies, the prevalence of PCL has been reported to range between 0.2% and 41.6% [4,10–17]. In a meta-analysis of 17 studies including 48,860 patients, the pooled prevalence of PCL was 8% (95% CI: 4–14%) [18]. Various factors influence the reported prevalence of PCL, including study-related factors and patient-related factors. Study-related factors include study design, imaging modality, and year of study. A recent study showed that incidental PCL were

documented in only 31% of radiology reports [11]. Thus, retrospective studies based on review of radiology reports rather than review of images underestimate the prevalence rates of PCL. Type of imaging modality also affects the prevalence rate, with increasing prevalence rates reported in studies using US, CT, MRI, and EUS, respectively [17,19]. Older studies report lower prevalence rates compared to newer studies. For instance, PCL were identified in 1.4% of abdominal scans in a study from 1980 [20], compared to 9.3% in a recent study from 2015 [7]. Higher prevalence in the newer studies is likely to be due to better quality of cross-sectional imaging hardware and software. In an interesting study by Moris et al., newer versions of MRI hardware and software were independently associated with higher PCL detection rates [4].

Risk Factors

Age

The likelihood of a PCL being present increases with age (Fig. 80.2). In general, when study populations consist primarily of older individuals the reported prevalence is high. For example, an autopsy series reported PCL prevalence of 24.3% in a population with a mean age of 79.3 years [16]. A study based on MRI in asymptomatic individuals with a mean age of 51.1 years, the prevalence was 2.4% [14]. PCL are infrequent under the age of 40 years; the prevalence in this age group varies from 0–1.2%, depending on the imaging modality used to identify PCL [12,13]. However, in one study using single-shot fast spin-echo MRI sequence, the overall prevalence of PCL was 9.1% in this age group [21]. The risk rises gradually over age 40 years. In a large study the odds of a PCL being present increased by 1.06 for each additional year after age 40 [12]. In individuals over 70 years, up to 40% patients appear to have a PCL [11]. In older patients, not only does PCL prevalence increase, but also the size and number of cysts increases [11,21]. In addition, compared to younger patients, older patients have a greater likelihood of finding malignant pathology and a greater probability of undergoing pancreatic surgery for PCL [22].

Gender

Although one study showed greater prevalence of PCL in women [23], most studies have not shown any difference in prevalence of PCL between the two sexes [11,12,14,15]. Most studies have not shown a difference in size of PCL between men and women [11,14,22], except one study, which showed larger cyst size in men compared to women [12]. There is no difference between rates of malignancy and number of PCL between the sexes [11,22].

Race and Geography

There are limited data on prevalence of PCL based on racial background. Only one study showed that the cysts are 3.5 times more prevalent in Asians compared to non-Asians after controlling for age as a risk factor [12]. Although the prevalence was higher in Asians, cyst size, location, or number was not different compared to non-Asians. In an autopsy study from Japan the prevalence was 24.3% [16]. By contrast, in an ultrasound-based study from Japan the prevalence was 0.21%. In a study from the Netherlands, MRI done in asymptomatic individuals showed a prevalence of 2.4% [14]. In a recent study based on CT scans from San Marino, prevalence in asymptomatic individuals was 5.4% [7]. The estimated standardized population prevalence for the state of San

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Marino was 2.2% [7]. An MRI study from Brazil reported a prevalence of 9.3% [13]. Studies from the United States have shown a prevalence rate of 1.2–19.6% [11,12,21]. The estimated pooled prevalence of PCL appears to be higher in US studies compared to Europe and Asia [18]. It is unclear if this difference in prevalence is due to geographical factors, since various other factors that could impact prevalence, such as age and modality of imaging, were not adjusted.

Family History of Pancreatic Cancer

Based on a case-control study, PCL were reported to be nearly three times more common in individuals with a first-degree relative who had pancreas cancer [15]. A multicenter US screening study in high-risk individuals for pancreatic cancer, such as individuals from familial pancreatic cancer families, hereditary pancreatitis, familial atypical multiple mole melanoma, familial breast–ovarian cancer with breast-related cancer mutation, and hereditary nonpolyposis colorectal cancer, and Peutz–Jeghers syndrome have shown a prevalence of 42% with multiple modalities—CT, EUS, and MRI [19]. The prevalence increased with age, as nearly 65% high-risk individuals over 70 years of age were noted to have a PCL. Another similar study from Sweden showed a prevalence of 40% in such high-risk individuals undergoing MRI screening for pancreatic cancer [24]. In the authors' experience, 5–10% of patients with PCL have a family history of pancreatic cancer in first-degree relatives. In patients with PCL, family history of pancreatic cancer in one first-degree relative is not associated with increased 5-year risk of pancreas cancer when compared to those without family history of pancreatic cancer [25]. Whether risk for pancreatic cancer is higher when there is more extensive family history of pancreas cancer is not known.

History of Pancreatitis

PCN such as IPMN can cause acute pancreatitis. IPMN have also been reported in patients with chronic calcifying pancreatitis [26]. Conversely, individuals with a history of pancreatitis can develop pseudocysts, which are often indistinguishable from PCN [27–29]. Given such issues, studies on the prevalence of PCL have typically excluded patients with a history of pancreatitis. Studies including patients with a history of pancreatitis have reported a prevalence of 16.6–42% [21,22]. However, whether these cysts represented pseudocysts or PCN was not known.

Miscellaneous

Recent studies have shown diabetes mellitus and insulin use as independent risk factors for PCL [15]. Presence of extrapancreatic cysts has also been strongly associated with PCL [4,14,21]. In a study, 70% patients with PCL had an extrapancreatic cyst [4]. The most frequent organs involved were kidneys (50%) and liver (50%). The presence of liver cysts is independently associated with PCL [14]. PCL are seen in 11% of solid organ transplant recipients [30]. Fortunately, pancreatic cancer is rarely seen in this group of patients. Lifestyle factors such as cigarette smoking and alcohol consumption are not associated with development of PCL [11–14,21,22].

PCL are seen in association with autosomal dominant polycystic kidney disease (ADPKD). About 5% to 10% of individuals with ADPKD have PCL, based on ultrasound [31]. However, ADPKD is rarely seen in patients with pancreatic cysts (~1%) [21]. In contrast, pancreas involvement is frequently seen in patients with von Hippel–Lindau disease (VHL). In a large French multicenter study, 77.2% of patients with VHL had pancreatic involvement, mostly PCL and typically serous cystic neoplasms and neuroendocrine tumors [32]. In 7.6% of these patients, the pancreas was the only organ involved. In this series, VHL patients with PCL had fewer pheochromocytomas than those without.

Cyst Size and Morphology

The majority of incidentally identified PCL are subcentimeter in size, the average cyst size being 8–10 mm [11–14,21]. However, cyst size increases gradually with age. For instance, in a study by Lee et al., the median cyst size in patients >90 years was 14 mm compared to 3 mm for those <39 years [11]. Large cysts (>3 cm) are infrequent, seen in <5% cases.

Among patients with incidentally identified cysts, almost half have more than one cyst [13,21]. Multifocal (>5) cysts have been reported in 10% to 40% of cases [13,14,21]. Cyst distribution is generally equal throughout the gland, with half the cysts located in the proximal part of the gland (head, neck, or uncinate) and the other half in the distal part of the gland (body or tail) [11,14].

Morphologically, the majority of PCL (80–90%) identified incidentally are simple in nature without any wall thickening, septations, or mural nodules [11,14]. Communication with the main pancreatic duct, which often implies a diagnosis of IPMN, is seen in 8% to 35% of cases [11,21].

Pancreatic Cystic Neoplasms

As discussed in the preceding section, although PCL are commonly identified, especially in older patients, most of these patients do not undergo surgery and therefore, their histologic diagnosis remains unknown. In one of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the largest surgical series of 851 patients at Massachusetts General Hospital undergoing surgery for PCL, IPMN were the most common PCN, seen in 38% of cases [5] (Fig. 80.3). MCN were the next most common (23%), followed by SCN (16%), cystic neuroendocrine tumors (7%), and SPN (3%).

IPMN are mucinous neoplasms arising from the pancreatic ducts. When they arise from the side branches, they are referred to as branch-duct IPMN (BD-IPMN) and are called main-duct IPMN (MD-IPMN) if they involve the main pancreatic duct. Mixed-IPMN involve both branch and main ducts, but for practical purposes they are considered together with MD-IPMN.

The median age of surgery for BD-IPMN is about 65 years with an almost equal distribution between males and females [33]. However, studies from Asia have reported male sex predilection with a 3 : 1 ratio [34]. The median size of resected BD-IPMN varies between 2 to 3 cms [33,35]. BD-IPMN appear as a solitary cyst, multifocal cysts, or a cluster of cysts. They arise from the side branches of the pancreatic duct, although the communication with the main pancreatic duct may not always be discernable on imaging. Almost 60% are in the head of the pancreas and 40% in the body/tail region; 15–40% are multifocal [33,35]. Malignancy is present in less than 20% of surgically resected cases [33,35]. About 12% have a history of pancreatitis and 35% have a history of smoking [33,35].

Similar to BD-IPMN, the median age for MD-IPMN is between 65 and 70 years [5]. They appear as dilation of the main pancreatic duct without any obstructing mass or stricture. The majority (64%) are in one location, most commonly in the head of the pancreas [3,5]. Among the 36% involving multiple locations, almost half have diffuse involvement of the entire pancreatic duct [3]. Malignancy can be seen in up to 60% of MD-IPMN, and is associated with older age, jaundice, and new-onset diabetes mellitus [3]. The malignancy risk in mixed-IPMN is like MD-IPMN.

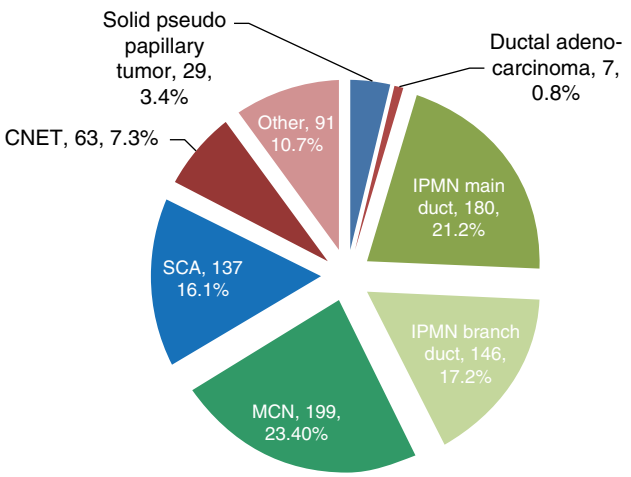

Figure 80.3 Distribution of pathologic diagnoses in 851 resected cystic neoplasms of the pancreas. Lesions classified as "other" included pseudocysts, 25; benign epithelial cysts, 11; acinar cell cystadenomas and cystadenocarcinomas, 3; lymphoepithelial cysts, 5; choledochal cysts, 4; lymphangiomata, 4; hemangiomata, 2; and other unclassified epithelial cysts. *Source:* Reproduced from [5], Fig.1/with permission of Elsevier.

MCN are almost exclusively seen in females (>95%) [36–39]. The median age is 40–50 years, and most patients are <60 years [36–39]. The median size of MCN typically varies between 5 cms to 10 cms [36,39]. MCN with an associated invasive carcinoma are generally larger than benign MCN and an associated invasive carcinoma is rarely seen in MCN <4 cms [36,39]. These PCN are solitary and often have septations and a thick wall. Wall calcification can be seen in about 25% of cases [37,38]. They are almost always (>90%) located in the body/tail region of the pancreas [36–39]. Less than 5% have communication with the main pancreatic duct [38]. An associated invasive carcinoma at the time of surgical resection is found in 10–20% [37–39]. Older age, larger cyst size, presence of mural nodules, and elevated CA-19-9 are associated with malignant transformation [36–39].

SCN are seen more commonly in females (75%) and the median age is 58 years [1]. Their median size at diagnosis is about 3 cms [40]. They are solitary, and generally appear as a cluster of multiple cysts separated by thin fibrous septae with a characteristic central scar seen in 30% of cases [41]. The pattern of cysts is microcystic in 45%, macrocystic in 32%, both microcystic and macrocystic in 18%, and solid in 5% of cases [1]. Cyst calcification is seen in about 15% of cases [1]. They are equally distributed in the pancreas with 40% in the head, 34% in the body, and 26% in the tail [1]. Malignancy is very rare (0.1%) [1].

SPN are predominantly seen in females (>85%) [42,43] and the median age of diagnosis is 35 years [43]. They are typically large at the time of diagnosis with an average size of 8.5 cms [42]. They are solitary, well encapsulated, round-oval, and have a variable amount of solid and cystic component, hemorrhage, and necrosis [43,44]. Cyst calcification can be seen in nearly half the cases [44]. They are equally distributed between the head, body, and tail of the pancreas [43]. Metastases can be seen in 15–20% of cases at surgery [43,44].

Cystic pancreatic neuroendocrine tumors present at a median age of 55–60 years and are equally distributed between the sexes [45,46]. The mean size varies between 2 to 5 cms [45,46]. These are typically solitary cystic lesions with a varying degree of solid/cystic component. Most have arterial hyperenhancement of solid component, as is seen with other solid neuroendocrine

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. tumors of the pancreas [45,46]. Nearly half of these have a characteristic hypervascular rim noted as an enhancing cyst wall on imaging [45]. Calcification is infrequent [46]. They can be seen in association with von Hippel–Lindau and multiple endocrine neoplasia (MEN) syndromes [45,46].

Introduction

With the increased use of cross-sectional imaging in the workup of numerous abdominal complaints, cystic lesions of the pancreas have been increasingly identified. The prevalence of incidental pancreatic cystic lesions in the adult population is high, and ranges from 2.6% to 19.6% [1]. Autopsy series report an increase in pancreatic cystic neoplasms prevalence with age: 8% in patients <70 years of age, up to 35% >90 years of age [2]. In the clinical practice, only 5% to 15% of pancreatic cysts have been reported as neoplastic (Table 81.1) [3]. Recently, most pancreatic cysts are considered to be small intraductal papillary mucinous neoplasms (IPMN) or retention cysts. Cystic neoplasms, including serous cystic neoplasms (SCN), mucinous cystic neoplasms (MCN), IPMN, intraductal oncocytic papillary neoplasms (IOPN), solid pseudopapillary neoplasms (SPN), and some types of acinar cell neoplasms can be classified according to their malignant potential into benign, precursor, and malignant [4]. It is important to recognize pancreatic cystic neoplasms before an invasive carcinoma develops, especially in MCN and IPMN. MCN and IPMN show ductal differentiation of the neoplastic epithelium; however, the differentiation of epithelial cells in SCN and SPN has not been fully recognized. The histopathologic classification and staging of major cystic neoplasms are discussed in this chapter.

Serous Cystic Neoplasms

Serous cystic neoplasms (SCN) are almost always benign, and indolent pancreatic neoplasms composed of innumerable small cysts lined by epithelial cells showing a clear cytoplasm and round, uniform nuclei. Patients are usually women (female/male ratio: 7:3) with a mean age at diagnosis of 60 years [5–7]. Approximately 40% of SCN are incidentally detected by imaging studies at routine physical examinations or for other diseases. Other patients complain of symptoms related to local mass effects, such as abdominal pain, palpable mass, nausea, and vomiting. Patients with von Hippel–Lindau (VHL) syndrome are at an increased risk for development of serous cystic neoplasms. SCN are observed in 12% of patients with this syndrome [8]. Sporadic SCN have been found to feature somatic mutations in the *VHL* gene in 50% of cases [9].

Macroscopically, SCN are multilocular, large cystic neoplasms and their cut surface typically shows a well-circumscribed, sponge-like appearance (called "microcystic type") with a central scar (Fig. 81.1a). The size of the cysts is variable, and there are several variants described below. The cysts contain serous watery fluid. They usually do not communicate with the pancreatic larger ductal system.

Histologically, the cysts are separated from one another by thin fibrous septa and the internal surface of the cysts is covered by a monolayer epithelium (Fig. 81.1b). The lining epithelial cells have a clear cytoplasm and round, uniform, centrally located nuclei. Although a moderate nuclear pleomorphism is not unusual, necrosis and mitoses are not identified.

Because the cells contain large amounts of glycogen, they stain strongly with the periodic acid–Schiff (PAS) reaction, but only without diastase digestion. Immunohistochemically, the epithelial cells lining the cysts express cytokeratins (CK), such as CK7 and CK19, and epithelial membrane antigen (EMA), MUC6, inhibin alpha, and Glut1, but not CEA, trypsin, or chromogranin A [3,4].

Table 81.1 Classification of cystic lesions of the pancreas.

Cystic neoplasms – Epithelial
Serous cystic neoplasm
Mucinous cystic neoplasm
Intraductal papillary mucinous neoplasm
Intraductal oncocytic papillary neoplasm
Solid pseudopapillary neoplasm
Acinar cystic transformation
Acinar cell carcinoma (intraductal papillary variant)
Mature cystic teratoma
Cystic neoplasms – Nonepithelial
Lymphangioma
Cystic degeneration of the nonepithelial neoplasms
Nonneoplastic cystic lesions
Pseudocyst
Retention cyst
Lymphoepithelial cyst
Mucinous nonneoplastic cyst
Congenital cysts
Enterogenerous cyst
Endometrial cyst

According to the current World Health Organization (WHO) classification, serous cystadenomas are classified into microcystic serous cystadenoma, macrocystic (oligocystic) serous adenoma, solid serous adenomas, VHL-associated serous cystic neoplasms, and mixed serous-neuroendocrine neoplasms [4]. The lining epithelium of these subtypes of SCN is the same as that of the common type (microcystic type) of SCN. Serous cystadenocarcinoma (malignant neoplasm) is defined by the presence of distant metastases because SCN with locally aggressive features, such as direct invasion into adjacent tissues, can rarely recur or even metastasize [4–6].

The most important differential diagnoses, especially in the macrocystic type of SCN, are with the two mucinous neoplasms, MCN and IPMN.

Mucinous Cystic Neoplasms

Mucinous cystic neoplasm (MCN) occurs almost exclusively in women (male/female ratio: 1:10–20), arises in more than 90% of cases in the body-tail of the pancreas, and has no, or very infrequent, communication with the pancreatic ductal system [4,10]. The mean age at diagnosis is approximately 45 years. Like the other cystic neoplasms of the pancreas, growing numbers of MCN are being detected in asymptomatic patients through imaging studies.

Macroscopically, MCN present as a round mass with a smooth, intracystic surface and a fibrous pseudocapsule with variable thickness and frequent calcifications. The tumor size ranges from 2 cm to 35 cm in greatest dimension. The cut surface shows unilocular or multilocular tumor cysts (so-called "cyst-in-cyst appearance") that contain mucus, watery fluid, or hemorrhagic-necrotic material (Fig. 81.2a). The internal surface can be smooth or may present with papillary projections and/or solid nodules. The presence of larger dimension papillary projections and/or mural nodules correlates significantly with malignancy.

Histologically, MCN is composed of the following two distinct components: a mucinous epithelium and a densely cellular ovarian-type stroma (OS) that represents the entity-defining feature (Fig. 81.2b). The epithelium frequently displays areas with pseudopyloric,

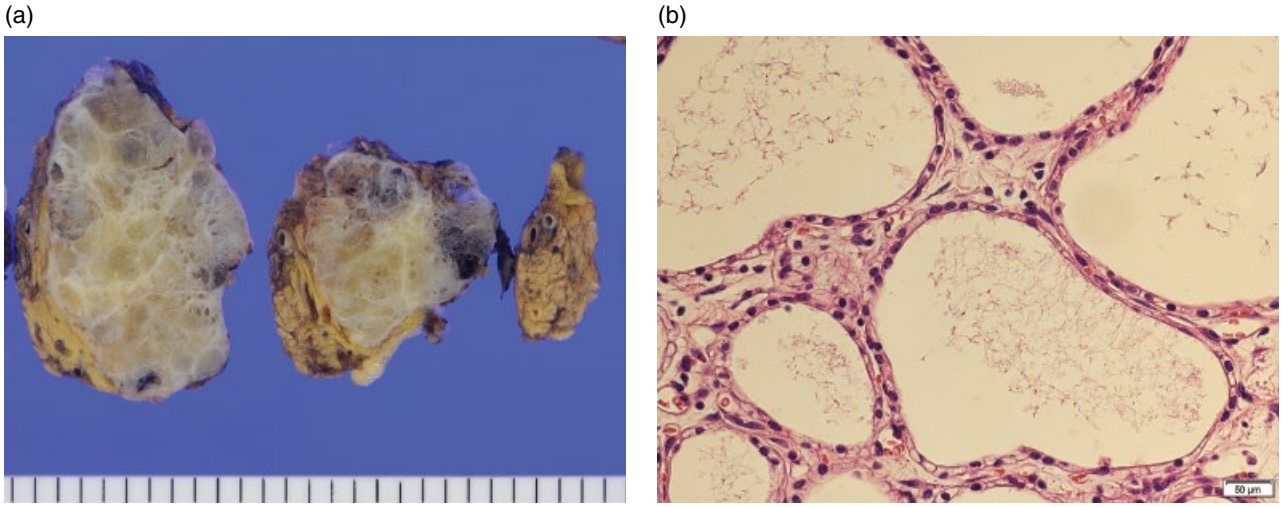

Figure 81.1 (a) Macroscopic feature of serous cystadenoma (microcystic type). The cut surface shows the well-circumscribed sponge-like appearance with a central scar. (b) Histology of serous cystadenoma (microcystic type). The internal surface of the cyst is covered by a monolayer epithelium. The lining cells show clear cytoplasm and small, round nuclei.

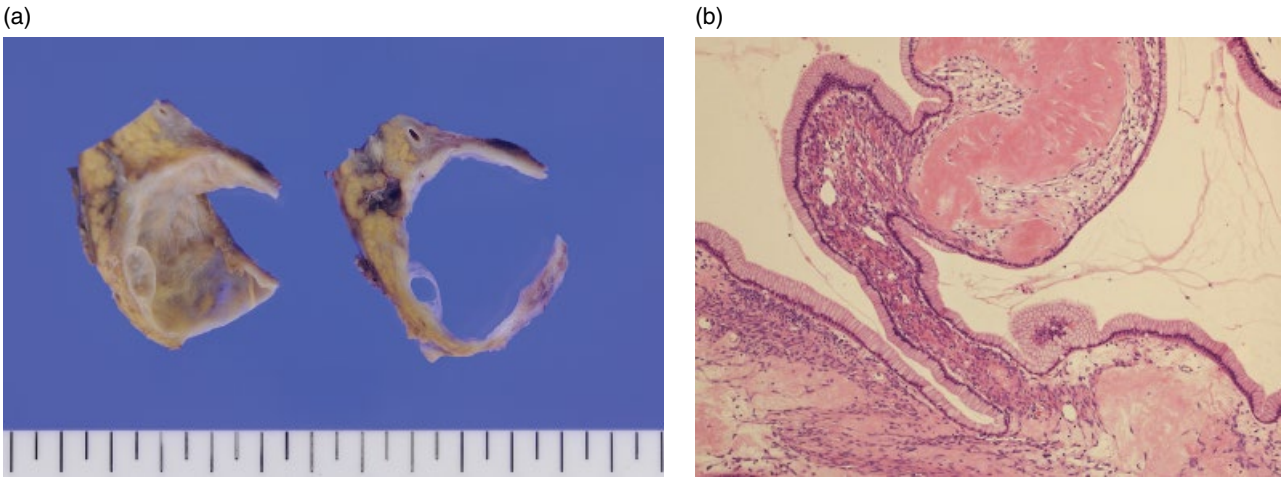

Figure 81.2 (a) Macroscopic feature of mucinous cystic neoplasm. The cut surface shows a "cyst-in-cyst appearance." (b) Histology of mucinous cystic neoplasm. MCN is composed of a mucinous neoplastic epithelium and a subepithelial densely cellular ovarian-type stroma.

gastric foveolar, and small and colonic intestinal differentiation. Noninvasive MCN are subcategorized into low- and high grades [4]. Low-grade MCN are characterized by a minimally dysplastic epithelium, whereas the high-grade MCN (the equivalent of carcinoma *in situ*) show papillae with irregular branching, budding, severe nuclear atypia, and frequent mitosis. The epithelial cells frequently show immunoreactivity for gastric foveolar type mucin marker MUC5AC, whereas MUC2 is only present in the goblet cells and MUC1 is usually expressed in high-grade MCN and invasive carcinomas.

The OS is a compact layer of cellular stroma that underlines the mucinous epithelium. It is constituted by spindle cells that show immunoreactivity for vimentin, smooth-muscle actin, progesterone receptors (PR), and estrogen receptors (ER). Occasional plump, eosinophilic cells, resembling luteinized cells and expressing alpha-inhibin, may be present. The presence of OS, currently requested for the diagnosis of MCN, in some cases can be hard to identify, because the OS can be replaced by a hyalinized stroma, secondary to a long history and high pressure-related atrophy.

Up to one third of MCN are associated with an invasive carcinoma, which usually resembles the common ductal adenocarcinoma, and colloid carcinomas are extremely rare [11,12].

The staging of the MCN with invasive carcinoma should be determined following the recent scheme proposed by Tanaka et al. [13]. The term "minimally invasive," that has been variably defined by different authors, should be avoided and replaced by the conventional staging protocols, including the AJCC/TNM [14]. The overall size of the invasive carcinoma should be recorded and categorized as early (≤2 cm, pT1) and advanced (>2 cm, pT2 and beyond). pT1 tumors should be subcategorized into pT1a (<0.5 cm), pT1b (0.5–1 cm), and pT1c (>1 cm) [13,14].

MCN have a potential to evolve into malignant tumors through low-grade to high-grade neoplasms [15]. The survival of invasive MCN may vary from excellent to 63% at 5 years [10,11]. Jang et al. [12], using the UICC/TNM staging, reported an aggressive clinical course with 3- and 5-year survival rates of 44% and 26%, respectively. Recent large-scale studies showed small (less than 4 or 5 cm in size) MCN with no symptoms or features of concern may safely be observed as a low risk of malignant transformation [15,16], though the neoplasms without radiologic features of malignancy tend to be resected.

Intraductal Neoplasm

Intraductal neoplasms of the pancreas are a heterogeneous category of radiographically and grossly detectable lesions defined as cystic or mass-forming epithelial neoplasms with ductal differentiation that grow primarily within the ductal system, and that can progress to invasive carcinoma.

According to the current WHO classification, intraductal neoplasms were classified into IPMN, IOPN, and intraductal tubulopapillary neoplasms (ITPN) [4]. Of these, ITPN is an important entity in the differential diagnosis of IPMN; however, this is usually not recognized as a cystic lesion [17]. The neoplastic epithelium shows nonmucinous and high-grade morphology. IOPN is a grossly cystic epithelial neoplasm composed of exophytic nodular projections lined by oncocytic glandular epithelium, which grows within dilated pancreatic ducts [4]. IOPN was previously classified as a subtype of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

IPMN; however, this neoplasm is now considered a distinct entity from IPMN according to the genomic abnormalities such as fusions in PRKACA and PRKACB genes [18,19].

IPMN are more common in men than in women. The mean age is approximately 65 years. Most IPMN are solitary and located in the pancreatic head, although 20–40% are multifocal. IPMN can be classified by several viewpoints, such as localizations (main duct or branch duct), histologic grading (low to high grade), histologic differentiation (gastric, intestinal, or pancreatobiliary), and mucin hypersecreting or not.

Macroscopically, IPMN is an intraductal neoplasm usually showing flat to papillary epithelial proliferation within the dilated pancreatic ducts (>1 cm) by abundant mucus (Fig. 81.3a). IPMN can be classified into main-duct type IPMN (MD-IPMN), branch-duct IPMN (BD-IPMN), and combined type IPMN according to the ductal portion of tumor involvement [4,13]. MD-IPMN typically show diffuse dilatation of the main pancreatic duct with abundant mucus and villous neoplastic components. BD-IPMN show multiple cystic dilatations of pancreatic ducts called "grape-like appearance." They arise more often in the head and neck and frequently involve the uncinate process. IOPN typically form relatively large, tan collar, friable papillary projections or solid nodules within cystically dilated pancreatic duct.

Histologically, the direction of differentiation of the neoplastic epithelial cells varies among IPMN, including gastric, intestinal, and pancreatobiliary types of differentiation. IPMN have varying degrees of cytologic and architectural atypia, and noninvasive IPMN can be categorized into low- and high grades with the same grading system as MCN. These various differentiations and grades of neoplasm are frequently mixed up within one neoplasm. Many intestinal-type IPMN arise in the larger pancreatic ducts, such as the main pancreatic duct (MD-IPMN), and usually show villous or high papillary projections of neoplastic epithelium with abundant extracellular mucus (Fig. 81.3b). If they invade outside the pancreatic duct, invasive components often form a colloid (mucinous) carcinoma. Intestinal-type IPMN show MUC2, MUC5AC, and CDX2 on immunohistochemistry. Gastric-type IPMN frequently occur in branch ducts (BD-IPMN).Their inner surface is covered by low papillary or flat neoplastic epithelium with low-grade dysplasia. Many of these gastric-type IPMN have an indolent course. Gastric-type IPMN are immunoreactive with MUC5AC and MUC6 in some cases. Pancreatobiliary-type IPMN characteristically grow with arborized pattern, and this type of neoplasm is immunoreactive with MUC1, MUC5AC, and MUC6 in some cases. These different phenotypes can be observed together, with the IPMN classified according to the predominant type. Despite similarities to IPMN, histology of IOPN is notable for complex, thick, arborizing papillae lined by multiple layers of cuboidal and columnar oncocytic (eosinophilic) mitochondria-rich epithelial cells. Based on both the architectural complexity and the degree of nuclear atypia, essentially all IOPN have high-grade dysplasia [4].

The 5-year survival rate for patients with a surgically resected IPMN without invasion is 90–95%. There are significant differences in the prevalence of invasive cancer between the MD-IPMN and the BD-IPMN. Carcinomatous transformation is reported in 30–50% of

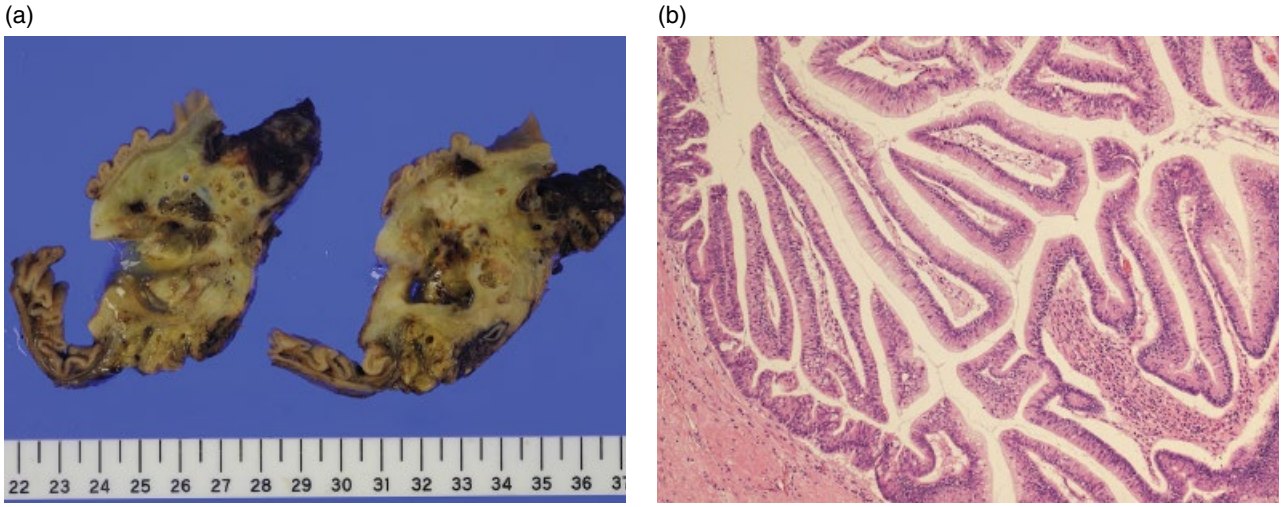

Figure 81.3 (a) Macroscopic feature of intraductal papillary mucinous neoplasm (main-duct type). The cut surface shows intraductal papillary lesions within the dilated main pancreatic duct. (b) Histology of intraductal papillary mucinous neoplasm (intestinal type). Intestinal type IPMN shows villous projections of neoplastic epithelium.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. MD-IPMN or mixed-IPMN, whereas the BD-IPMN have a lower risk of carcinomatous transformation, with 24% of surgically resected BD-IPMN found to have high-grade dysplasia or invasive adenocarcinoma [13]. Most of the invasive carcinomas that arise in MD-IPMN are colloid carcinomas, whereas tubular-type adenocarcinomas, characterized by the presence of malignant glands similar to conventional pancreatic ductal adenocarcinoma (PDAC), are associated with both pancreatobiliary-type IPMN and, in a small percentage, with gastric-type BD-IPMN. The type of invasive carcinoma has major prognostic implication: colloid carcinoma has a better prognosis than tubular adenocarcinomas, with the latter behaving like a conventional PDAC.

In contrast, approximately 10% of IPMN are concomitant with the conventional PDAC (histologically separated from the IPMN) [20]. Although the identification of the concomitant carcinomas has biologic (GNAS mutations) and prognostic (worse prognosis) relevance, at times their correct identification can be hard to achieve. The most frequent molecular anomalies of IPMN are either a *GNAS* or a *KRAS* mutation, and more than half IPMN have both mutations. The targeted genes found in PDAC, including *KRAS2*, *p16/CDKN2A*, *SMAD4*, and *TP53* genes, are found much less [21,22].

The stage of the invasive carcinoma, similarly to invasive MCN, is one of the most important prognostic parameters, and should be determined following the criteria suggested by Tanaka et al. [13] and the recommendations of the Consensus at the Verona meeting on IPMN [23]. The UICC/AJCC staging protocol is suggested, with their subcategorization of pT1 into pT1a (<0.5 cm), pT1b (0.5–1 cm), and pT1c (>1 cm).

Solid Pseudopapillary Neoplasm

Solid pseudopapillary neoplasm (SPN) of the pancreas is a low-grade epithelial neoplasm primarily occurring in girls and young women (20–40 years) and shows solid and cystic areas at macroscopy and pseudopapillary and poorly cohesive features at histology [4,24].

Macroscopically, SPN are frequently large, round, well-circumscribed masses and show variable proportions of solid and cystic areas filled with hemorrhagic fluid and necrotic debris (Fig. 81.4a). At the extreme ends of the spectrum of macroscopic appearances, some cases can be exclusively solid (usually the smaller lesions), whereas others (usually the larger tumors) may be entirely cystic.

Histologically, the tumors are composed of a mixture of solid and cystic areas, usually surrounded by a fibrous capsule. The tumor cells, collected in solid areas or lining pseudopapillae, are monomorphous with round to oval nuclei and eosinophilic, granular cytoplasms (Fig. 81.4b). PAS-positive globules, stromal myxoid degeneration, necrotic changes with foam cells, and hemorrhage are distinctive features of SPN. Mitotic figures are virtually absent. Despite the well-demarcated gross appearance, infiltrative edges entrapping acinar cells and islets are common findings in SPN [24].

The histogenesis of SPN remains unknown. The neoplastic cells show positivity for the endocrine markers CD56, NSE, and occasionally for synaptophysin, but the staining for chromogranin is always negative. Similarly, staining for acinar and ductal markers is consistently negative. Consistent positivity is present for vimentin, CD10, CD117, and progesterone receptors. Paranuclear dot-like immunostaining for

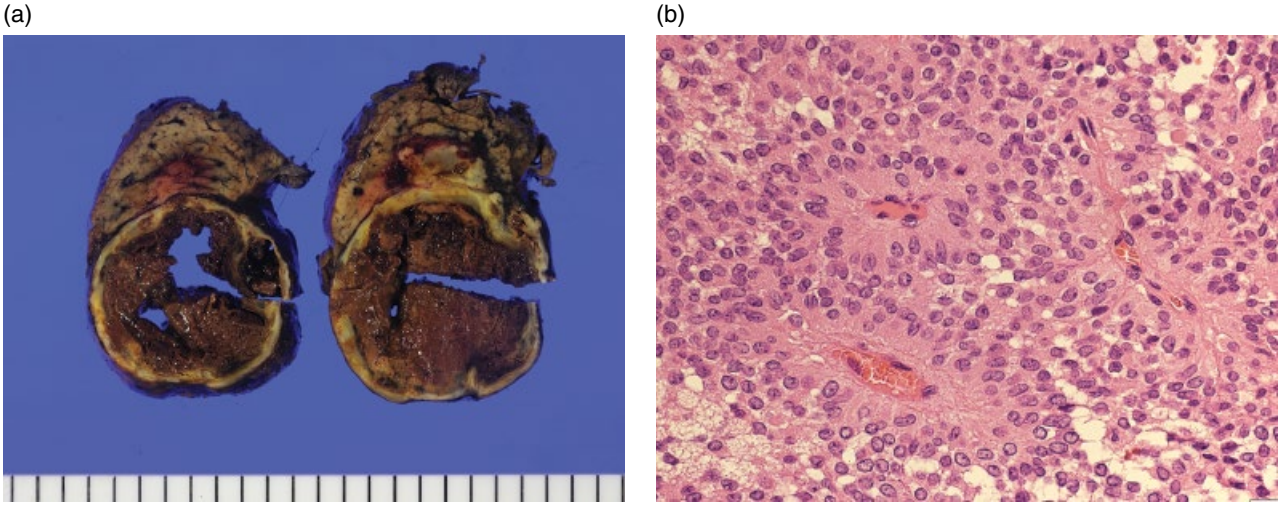

Figure 81.4 (a) Macroscopic feature of solid pseudopapillary neoplasm. The cut surface shows round, well-circumscribed masses with hemorrhagic and degenerative material. (b) Histology of solid pseudopapillary neoplasm. Solid area of the tumor shows pseudopapillary structures composed of monomorphous cells with round to oval nuclei and eosinophilic, granular cytoplasm.

CD99 is characteristic [25]. The most constant and diagnostically useful finding is the abnormal nuclear immunoexpression for β-catenin, which reflects the somatic point mutations in exon 3 of the β-catenin gene [26].

SPN are considered to be potentially malignant neoplasms, but most of the cases do not recur after complete resection of the tumor. Only 10–15% of cases progress aggressively, almost always involving the liver or the peritoneum. Even in such cases, the patients survive for many years. Only a few patients have died of a metastasizing tumor [23,24].

Acinar Cystic Transformation

Acinar cystic transformation, previously called acinar cyst adenoma, is a recently recognized cystic lesion lined by cells with acinar differentiation, and is believed to behave in a benign fashion [4]. Many of these lesions, particularly those that diffusely involve the gland, are considered not neoplastic [29]. The lining cells of the cystic inner surface lack atypia, and transitions between the cysts and preexisting acinar structures are often observed. Acinar cell carcinomas may rarely form intraductal papillary tumors.

Mature Cystic Teratoma

Mature cystic teratomas, also known as dermoid cysts, are rare, benign cystic neoplasms commonly composed of multiple cell types derived from one or more of the three germ layers (ectoderm, mesoderm, and endoderm). These cystic neoplasms are filled with thick, yellow, sebaceous material. Histologically, the cysts are lined by a simple ciliated or stratified squamous epithelium and skin appendages and other tissues, such as cartilage, bone, and brain, can be seen.

Molecular Mechanisms of Cystic Neoplasia-

Nickolas Papadopoulos and Ralph H. Hruban

Departments of Pathology and Oncology, The Sol Goldman Pancreatic Cancer Research Center, The Johns Hopkins University School of Medicine, Baltimore, MD, USA

Introduction

Cystic neoplasms of the pancreas can pose significant clinical challenges. Some cystic neoplasms are precursors to invasive pancreatic cancer and they therefore offer unique opportunities to save lives through early detection and early treatment [1]. However, other cystic neoplasms are entirely benign, and will never progress to invasive cancer. These harmless cystic neoplasms, because they can be hard to distinguish clinically from high-risk cystic lesions, present a real risk for over-treating patients [2–4].

While enhancements in imaging and years of clinical experience have improved the preoperative clinical classification of cystic neoplasms, currently available imaging technologies still have relatively poor sensitivity and specificity in diagnosing high-grade dysplasia, and there is still enormous room for improvement [5,6]. Simply put, too many pancreatic cysts are clinically misclassified, and when they are, patients can be harmed [2,3]. Preoperative misclassification of pancreatic cysts is the result of a lack of accurate classifiers compounded by the fact that sometimes a cyst of one type can radiographically mimic a different cyst type (Table 82.1). A common consequence of misclassification of a cyst is unnecessary surgery. The surgical resection of a benign pancreatic cystic lesion for the reason that it clinically mimics a potentially malignant tumor is a significant clinical problem, because pancreas surgery, even at high-volume centers, is associated with significant morbidity and even a 1–2% risk of operative mortality [2].

A great deal of effort has therefore gone into defining the molecular alterations underlying the development of the different pancreatic cyst types, with the hope that knowledge of these alterations may be translatable into clinical tests to determine cyst type and the need for surgery preoperatively.

All of the major cystic neoplasms of the pancreas have recently been well characterized at the molecular level, providing insights into the fundamental processes driving these tumors (Table 82.2) [7–9]. Importantly, studies in which both the cyst fluid and the tissue from the same neoplasm were available showed excellent concordance between the genetic changes present in the cyst fluid and in the tissue. Cyst fluid can be sampled at the time of endoscopy. Therefore, analysis of cyst fluid can be used preoperatively to identify genetic and epigenetic changes present in the neoplastic cells lining cysts, to aid in the classification of the cyst, and guide therapy [10–12A].

In this chapter we will review the molecular mechanisms driving each of the major types of cystic neoplasms of the pancreas, with emphasis placed on translating this new knowledge into patient care.

Serous Cystic Neoplasm

Serous cystic neoplasms (SCN) are cyst-forming neoplasms composed of uniform cuboidal neoplastic cells containing abundant glycogen [13]. Although SCN are benign and most can simply be observed clinically, many SCN are surgically resected because they cannot be distinguished clinically from potentially malignant cystic neoplasms. For example, the oligocystic variant of SCN forms large cysts, and these large cysts can clinically mimic other cystic neoplasms of the pancreas, particularly mucinous cystic neoplasms [2,13]. Similarly, the solid variants of SCN can mimic pancreatic neuroendocrine tumors.

The exomes of a series of well-characterized SCN have been sequenced [7,14]. SCN contain an average of 10 intragenic somatic mutations per tumor, and the *VHL* gene on chromosome 3p is mutated in ~50% of SCN [7]. These mutations are typically inactivating mutations.

Table 82.1 Identification of cyst type can be problematic.

Cyst type	Clinical characteristic	Clinical management goal	Reason for misclassification
SCN	Benign	Surveillance	Cystic SCN mimics MCN; solid SCN mimics PanNET
IOPN	A fraction progresses to malignancy	Surgery for high-grade; low-grade are rare	Can mimic other intraductal lesions
IPMN	A fraction progresses to malignancy	Surgery for high-grade; surveillance for low-grade	Difficult to determine grade preoperatively
MCN	A fraction progresses to malignancy	Surgery for most	Sometimes radiographically mimic SCN
SPN	Malignant	Curative surgery	Cysts associated with SPN can radiographically mimic other types of pancreatic cysts

IOPN: intraductal oncocytic papillary neoplasm; IPMN: intraductal papillary mucinous neoplasm; MCN: mucinous cystic neoplasm; PanNET: pancreatic neuroendocrine tumor; SCN: serous cystic neoplasm; SPN: solid pseudopapillary neoplasm.

Table 82.2 Types of cysts with their major genetic alterations.

	AVG # of intragenic mutations	CTNNB1	GNAS	KLF4	KRAS	PIK3CA	PRKACA/PRKACB fusions	RNF43	SMAD4	TP53	VHL
IOPN	–						X				
IPMN	27		X	X (LGD)	X	X		X	X (HGD)	X (HGD)	
MCN	16				X	X		X	X (HGD)	X (HGD)	
SCN	10										X
SPN	3	X									

HGD: high-grade dysplasia; IOPN: intraductal oncocytic papillary neoplasm; IPMN: intraductal papillary mucinous neoplasm; LGD: low-grade dysplasia; MCN: mucinous cystic neoplasm; SCN: serous cystic neoplasm; SPN: solid pseudopapillary neoplasm.

In addition, the neoplastic cells of SCN often have loss of heterozygosity (LOH) on chromosome 3p at the *VHL* locus, providing a "second hit" that inactivates gene function [7]. Germline mutations in the *VHL* gene can lead to the development of serous cystadenomas, as patients with the von Hippel–Lindau syndrome often develop serous cystadenomas of the pancreas [15]. As will be discussed later in the section on clinical implications, both *VHL* gene mutations and LOH on 3p are detectable in cyst fluid and cyst fluid analysis for these markers can therefore be used to characterize a cyst as an SCN [14].

The *VHL* gene codes for a protein, VHL, which functions in the hypoxia-induced factor (HIF) pathway [16]. The VHL protein forms a complex with other proteins, and this complex has E3 ubiquitin ligase activity, functioning in the ubiquitination and subsequent degradation of hypoxia-inducible factor alpha (HIFα) [16]. HIFα is a transcription factor that functions to control gene expression in response to cellular oxygen levels. HIFα stabilization created by the inactivating mutations in *VHL*, among other things, promotes the expression of a number of genes including vascular endothelial growth factor (VEGF), which in turn promotes angiogenesis and ultimately tumorigenesis [16].

The role of the VHL in the HIF1 pathway led Yip-Schneider and colleagues to hypothesize that vascular endothelial growth factor A (VEGF-A) levels may be elevated in SCN [17]. They therefore determined VEGF-A levels in cyst fluid samples obtained from surgically resected pancreatic cysts [17]. VEGF levels were determined by a simple enzyme-linked immunosorbent assay (ELISA) test. Although the number of cases they examined was relatively small, they found that VEGF-A levels are significantly increased in cyst fluid from SCN compared with cyst fluid from all other types of pancreatic cysts ($P < 0.0001$). They reported that VEGF-A has 100% sensitivity and 97% specificity as a biomarker for SCN [17]. Yip-Schneider and colleagues also found that the presence of a *VHL* mutation in the neoplastic cells of an SCN correlated with elevated cyst fluid VEGF levels. These studies nicely illustrate that both gene and protein markers can be useful clinically, and how genetic changes can be used to inform protein expression studies.

MicroRNA expression has not been well studied in SCN.

Intraductal Papillary Mucinous Neoplasm

Intraductal papillary mucinous neoplasms (IPMNs) are distinct mucin-producing neoplasms that are usually papillary and which, by definition and name, involve the pancreatic duct system [13]. IPMNs are common in the general population, especially in the elderly [18,19]. Imaging studies suggest that ~3% of the population has an IPMN [18,19]. A small fraction of IPMNs progress to invasive carcinoma, and it can be difficult to determine clinically which IPMNs need to be resected, and which can be safely followed.

Intragenic somatic mutations have been reported in a number of genes in IPMNs. These genes include *KRAS*, *GNAS, p16/CDKN2A, PIK3CA, RNF43, SMAD4*, and *TP53* [7,9,20].

KRAS (v-Ki-ras2; Kirsten rat sarcoma viral oncogene homolog) gene mutations are present in ~80% of IPMNs [7,9]. These are activating point mutations in codons 12, 13, or 61 of the *KRAS* gene. *KRAS* gene mutations activate a number of very complicated downstream pathways including the RAF (rapidly accelerated fibrosarcoma)/MAPK (mitogen-activated protein kinase) and phosphoinositide 3′-kinase (PI3′K) pathways [21–23]. Activated KRAS also upregulates the GLUT1 glucose transporter and alters the expression of enzymes involved in glucose utilization producing the so-called "Warburg effect" in the neoplastic cells [21–24]. In addition, activated KRAS signaling leads to constitutively high levels of autophagy [22]. All of these changes conspire to promote tumorigenesis.

Activating point mutations in the *GNAS* (guanine nucleotide binding protein [G protein] alpha stimulating activity polypeptide 1) gene, usually at codon 201 (R201C and R201H), are present in ~75 % of IPMNs [7–9]. *GNAS* mutations appear to be more common in IPMNs with "intestinal" differentiation than they are in IPMNs with "pancreatobiliary" or "gastric-foveolar" differentiation [9,25]. A *GNAS* mutation and/or a *KRAS* gene mutation are seen in >90% of IPMNs [8,9]. The *GNAS* gene codes for a protein that forms a protein complex which activates adenylate cyclase.

Several studies integrating *GNAS* and *KRAS* mutational analyses with tissue pathology have provided insight into IPMNs biology and clinical behavior. For example, IPMNs have historically been defined pathologically as lesions >1 cm, while smaller precursor lesions (<0.5 cm) are categorized pathologically as pancreatic intraepithelial neoplasia (PanIN) [26]. This leaves a large unclassified grey zone for lesions between 0.5 cm and 1.0 cm. PanIN lesions have not been shown to harbor *GNAS* mutations, while IPMNs do. Matthaei and colleagues therefore examined 21 lesions in the grey zone (0.5–1.0 cm) for *KRAS* and *GNAS* mutations [27]. *GNAS* mutations were identified in seven (33%) of these lesions, helping to define them as small ("incipient") IPMNs rather than large PanIN lesions [27]. As a result the new pathologic classification system for precursor lesions in the pancreas now includes the new term "incipient IPMN" for lesions ≤1.0 cm with histologic or genetic features of a larger IPMN [28].

The *PIK3CA* (phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha) gene codes for a protein that forms the catalytic subunit of the phosphatidylinositol 3-kinase (PI3K) enzyme. This enzyme activates a number of downstream functions that in turn promote cell proliferation and migration, and ultimately cell survival and tumorigenesis. *PIK3CA* gene mutations have been reported in 10% of IPMNs [9]. These mutations are, as was true for *GNAS* mutations, more common in IPMNs with intestinal differentiation.

Inactivating mutations in the *RNF43* gene are present in 30–70% of IPMNs [7,9]. The *RNF43* gene codes for a ubiquitin ligase protein that functions in the Wnt/β-catenin signaling pathway [29,30]. As will be discussed later in this chapter, the presence of genetic alterations of the *RNF43* gene in some IPMNs suggests that Wnt/β-catenin signaling is a potential therapeutic target for invasive carcinomas that arise from *RNF43* mutant IPMN [29,31].

The *KLF4* gene on chromosome 9q encodes for the transcription factor Kruppel-like factor 4. Hotspot mutations (K409 and S411) in the *KLF4* gene have been reported in slightly more than half of the IPMNs examined [20]. What is interesting about these mutations is that they are more prevalent in low-grade IPMNs than they are in high-grade IPMNs. The implications of this finding are not clear, but suggest that these *KLF4* mutations, while they promote proliferation, may not be sufficient to promote neoplastic progression.

SMAD4, *p16/CDKN2A*, and *TP53* are all tumor suppressor genes that have been reported to be inactivated in IPMNs [7,9,32]. The *p16/CDKN2A* gene, which encodes CDKN2A, an important regulator of the cell cycle, is inactivated in ~30% of IPMNs. The gene can be inactivated by intragenic mutation, usually a deletion or an inactivating mutation of one allele, coupled with loss of the second allele, and in additional cases by hypermethylation of the gene's promoter [7,9,33]. Mutations in this gene can be seen in IPMNs with both low- and high-grade dysplasia [32]. By contrast, *SMAD4* and *TP53* inactivation appear to be late genetic events, and are found in IPMNs with high-grade dysplasia and in invasive carcinomas that rose in association with an IPMN [7,9,32].

Studies of the genetic alterations present in the noninvasive and invasive components of IPMNs have shown that the invasive and noninvasive components virtually always harbor identical mutations [7,9,32]. This finding

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

helps establish that invasive carcinomas can arise from IPMNs (they are not chance coincidental lesions). Furthermore, low-grade IPMNs contain multiple genetic clones, and a dominant clone emerges as the neoplasm progresses to high-grade dysplasia [34,35].

Recent molecular analyses of a histologic variant of IPMN, the intraductal oncocytic papillary neoplasm (IOPN), have identified novel fusion genes that characterize this tumor type [36,37]. In particular, Singhi and colleagues found recurrent fusions of *ATP1B1-PRKACB*, *DNAJB1-PRKACA*, or *ATP1B1-PRKACA* in IOPN [36]. While virtually all IOPNs harbor one of these fusion genes, these rearrangements were absent from all of the IPMNs Singhi and colleagues examined [36].

The expression of a number of microRNA is dysregulated in IPMN. These microRNA may have important biologic functions in the neoplasms, and some may be useful clinical markers [38–42]. For example, Matthaei and colleagues compared the expression of 750 microRNA in a series of microdissected IPMNs to their expression in normal ductal epithelium and identified a panel of microRNA that have the potential of being used to distinguish IPMN with low-grade dysplasia from IPMN with high-grade dysplasia [38]. Similarly, Caponi and colleagues found that miR-21 and miR-155 are upregulated in IPMN with an associated invasive carcinoma, as compared with IPMN without an invasive carcinoma, and, conversely that miR-101 levels are higher in IPMN without an invasive component than in IPMN with an invasive component [42]. Going a step further, Matthaei and colleagues also identified a panel of microRNA that could help distinguish IPMNs from other types of cysts in the pancreas [38]. Of note, microRNA can be identified in cyst fluid samples, suggesting that quantifying microRNA levels in cyst fluid aspirated at the time of endoscopy could be used to improve the clinical classification of pancreatic cysts [38,40].

A number of alterations in protein and glycoprotein expression have also been reported in IPMNs [43–48]. As is true for microRNA, several proteins and glycoproteins are differentially expressed in IPMNs with low-grade as compared to IPMNs high-grade dysplasia, and most are detectable in cyst fluids [43–45]. Pandey and colleagues have established a useful online resource that summarizes many of the proteins whose expression is altered in invasive pancreatic cancer, and the expression of many of these proteins is also altered in IPMNs [46].

Mucinous Cystic Neoplasm

Mucinous cystic neoplasms are mucin-producing and cyst-forming neoplasms that contain a characteristic ovarian-type stroma [13]. In contrast to IPMNs, the cysts of MCNs almost never communicate with the main duct system of the pancreas [13]. As is true for IPMNs, only a fraction of MCNs progress to invasive carcinoma.

Many of the genes targeted in IPMNs are also targeted in MCN [7]. These genes include *KRAS*, *RNF43*, *PIK3CA*, *p16/CDKN2A*, *SMAD4*, and *TP53* [7]. The major difference is that, in contrast to IPMNs, the *GNAS* gene is rarely, if ever, targeted in MCNs. The function of these genes is described in detail above in the section on IPMNs.

Just as the genetic alterations found in IPMN have proven useful, so too have a number of groups attempted to use the genetic alterations in MCNs clinically. As noted earlier, oligocystic serous cystadenomas can mimic MCNs, and, as a result, some benign serous cystic neoplasms are surgically resected [13]. There is therefore a great clinical need to distinguish between these two entities. The initial clinical results using molecular approaches to distinguish between serous cystic neoplasms and MCNs are not as promising as they are with IPMNs [50]. For example, Singhi and colleagues tested 546 pancreatic cyst fluid samples obtained by fine-needle aspiration at the time of endoscopic ultrasound (EUS) for *KRAS* gene mutations and found that although *KRAS* mutations had a specificity of 100% and a sensitivity of 54% for mucinous differentiation (IPMN and MCN), the sensitivity was only 14% when limited to MCNs [50]. However, with improvements in methodology, addition of more genes, and new algorithms the sensitivity of detecting MCNs has increased significantly [7,11].

The patterns of microRNA expression in MCNs have been studied, and as is true for the genetic mutations, there is some overlap with IPMNs [40]. For example, mir-21 is elevated in MCNs [40].

Solid Pseudopapillary Neoplasm

Solid pseudopapillary neoplasms (SPNs) are epithelial neoplasms composed of poorly cohesive, relatively uniform, neoplastic cells [13]. Although all SPNs are now classified as malignant, the vast majority (~90%) of patients with an SPN can be cured with surgical resection [13].

The exomes of a series of well-characterized SPNs have been sequenced, and, quite remarkably, virtually all SPNs harbor a *CTTNB1* (β-catenin) gene mutation, and practically no other genetic alterations [7,51,52]. The *CTTNB1* mutations observed prevent the degradation of the β-catenin protein, which is then translocated from the cytoplasm to the nucleus. In the nucleus β-catenin functions to activate the Wnt (int/Wingless) signaling pathway, which in turn mediates gene expression through the lymphoid enhancer-binding factor 1 (LEF1) /T-cell factor transcription complex [53]. Indeed, Singhi and colleagues have shown that *CTTNB1* gene mutations strongly correlate with LEF1 nuclear overexpression in

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

SPNs [53]. The combination of immunolabeling for LEF1 (expressed in SPN) and INSM1 (expressed in pancreatic neuroendocrine tumors [PanNet]) has proven useful in distinguishing SPNs from PanNETs [54].

Of interest, SPNs are also characterized by alterations in E-cadherin expression, including loss of expression of the extracellular domain of the E-cadherin protein [55,56]. Recently Huels and colleagues have suggested that reduced E-cadherin expression has a synergistic effect with activating mutations in β-catenin in promoting tumorigenesis [57].

Little is known of the changes in microRNA and protein expression in SPNs [58–60]. In large part this is because the normal cell type that corresponds to the neoplastic cells of SPNs is not well defined. Therefore, expression studies are challenged by the absence of a good control tissue/normal cell type. Several immunohistochemical labeling studies using a candidate marker approach have shown that CD99 and CD10 are overexpressed in SPNs, that the β-catenin protein is abnormally localized to the nucleus, and that E-cadherin expression is lost (when antibodies to the extracellular domain are used) or abnormally localized to the nucleus (when antibodies to the intracellular domain are used) [61,62].

Other Cystic Neoplasms of the Pancreas

For completeness sake we should mention that some typically solid neoplasms of the pancreas can present as cystic masses. For example, pancreatic neuroendocrine tumors (PanNET) can be cystic, as can some ductal adenocarcinomas [13]. These cystic variants appear to have the same molecular alterations as do the solid variants of these same tumors.

Clinical Applications

Several clinical applications of our growing knowledge of the molecular events that drive the formation of cystic neoplasms of the pancreas have been mentioned above, and here we focus on what we believe to be the most promising clinical applications close on the horizon.

First, the genes mutated in IPMNs can be used clinically to distinguish IPMNs from other neoplasms, and in so doing prevent unnecessary surgeries [7,8]. For example, as noted earlier, serous cystic neoplasms virtually never harbor *KRAS* or *GNAS* mutations, while one or both of these mutations is seen in 90–95% of IPMN [14]. Since mutant DNA present in neoplastic cells is shed into the cyst fluid, EUS aspiration of cyst fluid coupled with sequencing of the fluid for *KRAS* or *GNAS* mutations can be used to distinguish serous cystadenomas from IPMNs [14,50]. Furthermore, the cysts of IPMNs communicate with the pancreatic duct system, suggesting that a similar approach can be taken with sequencing secretin-stimulated pancreatic secretions ("juice") obtained in the duodenum at the time of endoscopy [63,64]. It is hoped that additional markers, such as *SMAD4* and *TP53* gene mutations and patterns of LOH and aneuploidy, will be useful in distinguishing IPMNs with low-grade dysplasia from IPMNs with high-grade dysplasia [14].

Second, some of the molecular alterations present in cystic neoplasms that progress to invasive carcinoma are potentially therapeutically targetable. As mentioned previously, a significant fraction of IPMNs and MCNs harbor *RNF43* gene mutations that are predicted to activate the Wnt signaling pathway [7,29,65]. A number of new agents, including selective inhibitors of the porcupine protein in the Wnt pathway, are being developed that could be effective in treating invasive pancreatic cancers that have *RNF43* mutations because they arose from a precursor IPMN with an *RNF43* mutation [29].

The *PIK3CA* gene functions in the mTOR pathway and *PIK3CA* is targeted in ~10% of IPMNs [9]. A number of agents targeting PIK3CA have been developed, and again, these agents could be effective in treating invasive pancreatic cancers that have *PIK3CA* gene mutations because they arose from an IPMN precursor with a *PIK3CA* gene mutation.

Implications for Families

Several familial cancer syndromes are associated with an increased risk of developing a pancreatic cystic neoplasm. Roberts and colleagues reported that almost 3% of patients with an IPMN harbor a deleterious germline mutation in a cancer predisposition gene [66]. Perhaps the greatest risk is seen in patients with the Peutz-Jeghers syndrome (PJS) [67]. Patients with PJS have a 130-fold increased risk of developing invasive pancreatic cancer, and Su and colleagues have demonstrated that some of these invasive cancers arise from noninvasive IPMN precursor lesions [68]. This suggests that patients with PJS may benefit from screening for early curable pancreatic neoplasms (noninvasive IPMNs) [69–71].

Although not strictly a "familial genetic syndrome," the McCune-Albright syndrome is caused by *GNAS* mutations acquired very early during embryogenesis [72,73]. Affected individuals harbor mosaic *GNAS* mutations, and ~15% of individuals with the McCune-Albright syndrome, in addition to the characteristic skin and bone changes, develop an IPMN, some of which progress to invasive carcinoma [72,73]. Of note, Parvanescu and

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

colleagues screened 272 patients operated on for an apparently sporadic IPMN and found a patient with polyostotic fibrous dysplasia and café-au-lait spots suggestive of McCune-Albright syndrome [72].

Finally, as noted earlier, germline *VHL* gene mutations cause the von Hippel–Lindau syndrome (VHL), and patients with VHL frequently develop serous cystadenomas of their pancreas [15]. Fortunately, these are virtually always benign.

Conclusions

It is clear that there is a clinical need to better classify cysts preoperatively. Current guidelines do not appear to be adequate [74]. Molecular analyses of cystic neoplasms of the pancreas have helped validate the existing histologic classification of these cysts, and have provided new opportunities to improve the clinical management of patients with a cystic tumor of the pancreas.

Clinical Presentation of Pancreatic Cystic Neoplasms

Masao Tanaka

Kyushu University, Shimonoseki City Hospital, Shimonoseki, Yamaguchi, Japan

Introduction

A variety of pancreatic neoplasms show a cystic form. Some of them are originally grow in a cystic form (Group A), including intraductal papillary mucinous neoplasm (IPMN), mucinous cystic neoplasm (MCN), serous cystic neoplasm (SCN), and solid pseudopapillary neoplasm (SPN). Some others are cystic degeneration of solid neoplasms (Group B), consisting of cystically degenerated neuroendocrine neoplasm, acinar cell carcinoma, pleomorphic carcinoma, adenosquamous carcinoma, leiomyosarcoma, Schwannoma, and malignant fibrous histiocytoma. There are some rare types of pancreatic cystic tumors which may be misidentified as cystic neoplasms but are not really neoplastic (Group C), including epidermoid cyst arising in the intrapancreatic accessory spleen and lymphoepithelial cyst. Like this, many entities arising in the pancreas may form a cystic pattern, but those in Group A are within the scope of this chapter.

Most cystic neoplasms are asymptomatic and diagnosed by chance when a patient undergoes imaging diagnostic studies such as ultrasonography, computed tomography, and magnetic resonance imaging performed for a health check or investigation of some other diseases. Some cystic neoplasms of the pancreas, however, may present with vague abdominal symptoms such as epigastric discomfort and fullness of the stomach when the neoplasm grows very large. Rather rare events of cystic neoplasms of the pancreas are acute pancreatitis when the neoplasm *per se* or its product causes obstruction of the main pancreatic duct. This may happen when a branch duct IPMN expels mucin into the nondilated main pancreatic duct, resulting in obstruction of the main duct.

Intraductal Papillary Mucinous Neoplasm

IPMN is a precancerous lesion that is most frequent in all cystic neoplasms of the pancreas [1]. IPMN are classified into three morphologic types: (i) branch-duct type (BD-IPMN), which only involves the pancreatic duct branches; (ii) main-duct IPMN (MD-IPMN), which involves the main pancreatic duct; and (iii) mixed-type IPMN, which is mixture of BD-IPMN and MD-IPMN [2]. The morphologic classification is important to predict the probability and potential of malignant transformation of IPMN. BD-IPMN have a low risk for progression to cancer, whereas MD- and mixed-type IPMN are more liable to cancerous changes [1].

When a pure BD-IPMN produces a lot of mucin, a mucin plug expelled from the IPMN into the main pancreatic duct may block the duct especially at its outlet. The blockade may cause acute pancreatitis that is usually mild to moderate, transient, and self-limiting but sometimes severe (Fig. 83.1). When this phenomenon occurs frequently, the patient may be advised to undergo pancreatic resection to remove the IPMN. If there is no risk of malignant changes (no high-risk stigmata or worrisome features), resection may be limited to the cyst and connecting ductal branch [3]. However, most centers perform partial or segmental pancreatectomy to avoid pancreatic leak as a complication of nonanatomical limited pancreatic resection as much as possible. Resection of the IPMN is also acceptable as symptomatic BD-IPMNs are more prone to malignant transformation [4].

Likewise, epigastric pain or discomfort due to chronic pancreatitis or its acute exacerbation may occur due to mucin plugs produced in the main pancreatic duct by MD- or mixed-type IPMN. Less frequently, obstruction of the

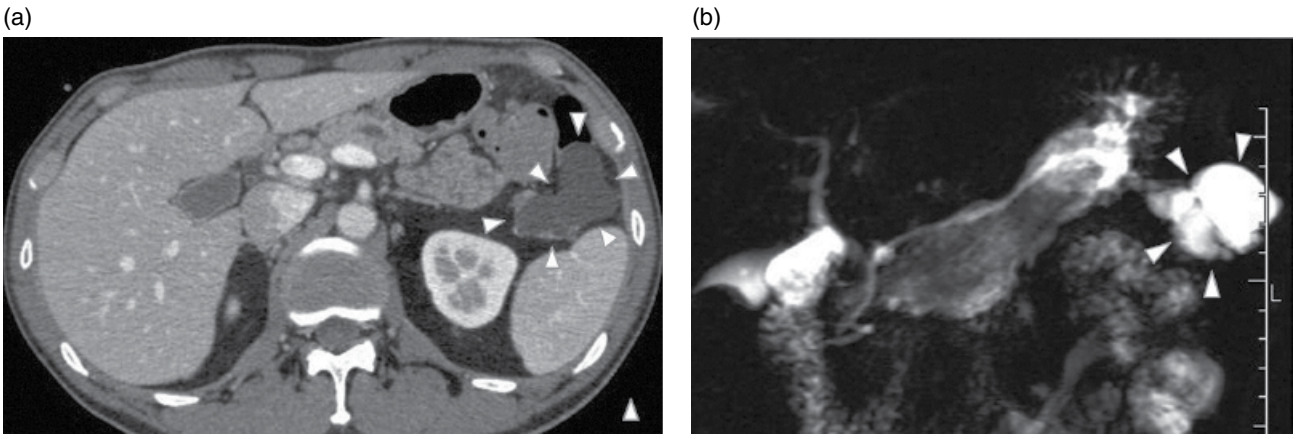

Figure 83.1 A 5.5 × 4.0-cm intraductal papillary mucinous neoplasm (arrowheads) in the pancreatic tail causing recurrent episodes of acute pancreatitis in a 51-year-old man. (a) Dynamic CT. (b) MRCP.

common bile duct may develop due to inflow of mucin when a large IPMN with invasive cancer invades and penetrates the bile duct wall, resulting in jaundice and/or cholangitis. However, the advent and wide availability of modern imaging technologies that promote early diagnosis of IPMN have made these symptoms very rare.

Mucinous Cystic Neoplasm

A vast majority of MCN have no connection with the main pancreatic duct. This feature has been regarded as one of the characteristics to distinguish MCN from BD-IPMN [2,5]. However, a recent study reported that 18.1% of 156 patients with MCN histologically proven by the presence of ovarian-type stroma had a communication between the cyst and pancreatic duct [6]. Unexpectedly, as many as 47% of 153 patients with MCN were symptomatic and 10 patients (6.6%) had a history of acute pancreatitis. Unfortunately, however, details of the clinical symptoms were not described and, moreover, the association of acute pancreatitis and the presence of communication to the pancreatic duct were not described in this study.

Xourafas et al. [7] compared clinical characteristics of 47 patients with noninvasive MCN and 87 patients with noninvasive IPMN. Those with MCN were more often female, significantly younger, more symptomatic, and had cysts more often located in the pancreatic tail. MCN may present with some clinical symptoms more frequently than previously thought.

The symptoms associated with MCN are usually caused by compression of nearby organs. Although compression on the common bile duct might cause jaundice, only one of 156 patients with MCN reported by Yamao et al. [6] had the tumor in the head of the pancreas. Other symptoms include a palpable mass, abdominal pain or discomfort, and rarely general fatigue and weight loss. Left pleural effusion may be associated with a large MCN (Fig. 83.2). Sperti et al. [8] reported two patients with MCN whose clinical presentation was an attack of acute pancreatitis and called attention to possible misdiagnosis as a pseudocyst. MCN should also be taken into consideration in a patient with a cystic formation in the body and tail of the pancreas after acute pancreatitis.

MCN exerts an adenoma–carcinoma sequence. Mucinous cystic carcinoma is usually large and has mural nodules within the cyst. It may present with nonspecific symptoms in the upper abdomen due to its large size. In the series of 156 patients with MCN reported by Yamao et al. [6], 3 patients did not provide the information. Of the remaining 153 patients, 7 (4.6%) had diabetes mellitus, similar to 3.8% previously reported by Thompson et al. [9]. This would be pancreatic diabetes secondary to parenchymal replacement by a large MCN or obstructive pancreatitis caused by an MCN. Very rarely, MCN contains gastrin-producing cells causing hypergastrinemia and Zollinger-Ellison syndrome as rarely seen in ovarian MCN as well [10,11].

Serous Cystic Neoplasm

Most of SCN grow very slowly and remain asymptomatic. A large series of 172 patients with SCN reported by a study group of the Japan Pancreas Society included 90 patients with resection and 82 under observation [12]. Thirty-nine percent of SCNs were located in the head, 35% in the body, and 22% in the tail of the pancreas. The mean size of SCN was 4.1 cm. Of these, only 20% were symptomatic. Small SCN invariably remain asymptomatic. The symptoms if any are largely nonspecific such as nausea, vomiting, and abdominal discomfort caused by mass effects and/or

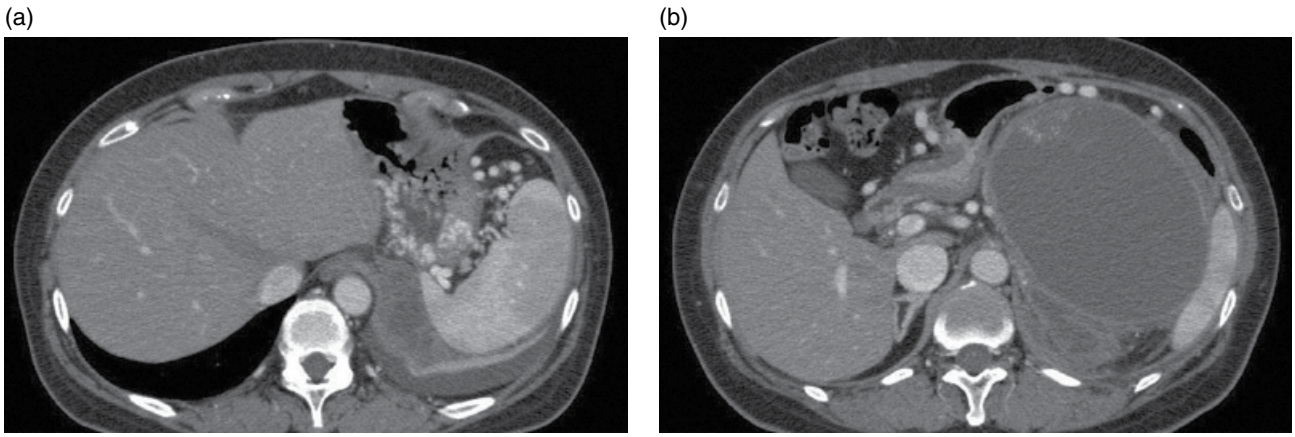

Figure 83.2 A 13-cm mucinous cystic carcinoma in a 56-year-old woman presenting with left pleural effusion. (a) Dynamic CT showing dilated perigastric collateral veins and gastric varices resulting from obliteration of the splenic vein. Left subphrenic fluid collection and pleural effusion are also observed. (b) Another image delineating a thick-walled huge cyst with an enhanced mural nodule.

compression to the main pancreatic duct. When the tumor grows huge, it may become palpable. It may also cause acute and/or chronic obstructive pancreatitis, or onset or deterioration of diabetes mellitus. Jaundice may occur when an SCN located in the head of the pancreas has enlarged and occluded the common bile duct; however, this is also a very rare event, occurring in only one of 172 patients [12]. In most cases, surrounding structures would detour as much as possible even if the SCN should grow large.

Solid Pseudopapillary Neoplasm

SPN is a benign or low-grade malignant neoplasm largely found in children or young women. Approximately 90% of patients are female, and the median age of all patients at diagnosis is 25–30 years. Although abdominal discomfort or dull pain may bring a patient with SPN to medical attention, most of the patients are diagnosed by chance on routine physical examination or imaging studies for a screening or other purpose. In symptomatic patients a palpable mass is the most common presentation (Fig. 83.3). Lee et al. [13] reported 62 patients with SPN. A mass was palpable in 60% of 15 pediatric patients and 40% of 47 adults. The tumor tended to be larger in children than in adults. Abdominal discomfort with or without dull pain was claimed in 58% of another series of 62 patients reported by Cai et al. [14]. A palpable mass was noticed in 15%. In a later series of 45 patients, Dai et al. [15] described clinical presentation in 44 female and 1 male patients with a mean age of 32.2 years. Abdominal pain was present in 37.8%, abdominal

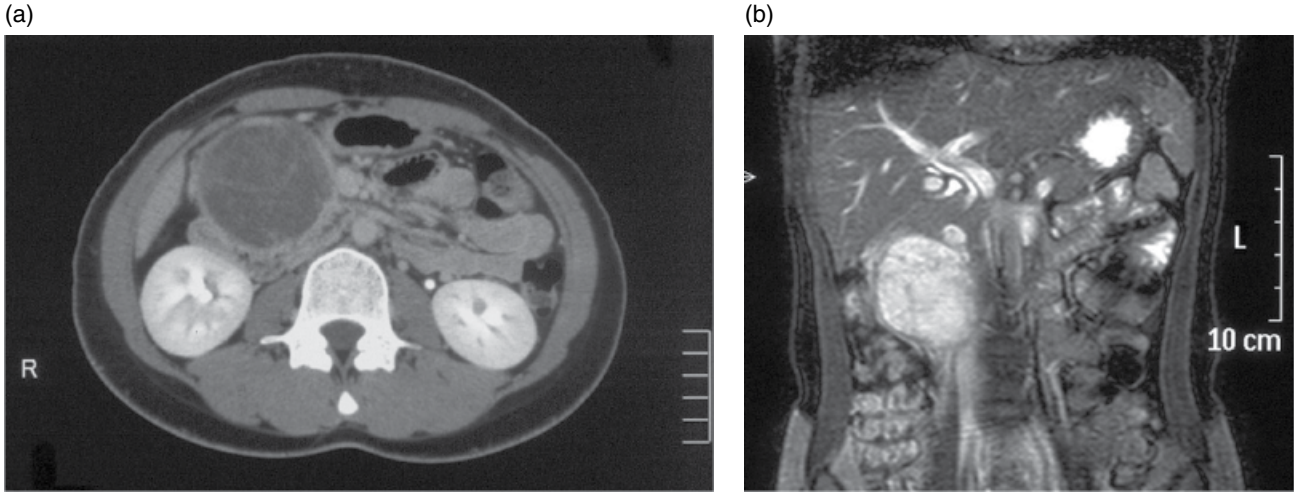

Figure 83.3 A solid pseudopapillary neoplasm in the pancreatic head in a 21-year-old female student. (a) Delayed phase of dynamic CT showing an 8.5-cm encapsulated cystic tumor with enhanced components. (b) Sagittal plane of T2 weighted MRI demonstrating heterogenous structure of the tumor.

distension 31.1%, back pain 13.3%, and vomiting 8.9%. All four patients with the incidental diagnosis of an SPN were asymptomatic in their series.

The mass effect of SPN sometimes affects the main pancreatic duct and common bile duct; however, jaundice is very rare even when the tumor is in the head of the pancreas. Rupture of an SPN may occur very rarely, causing severe abdominal pain, hemoperitoneum, and hypotension [16,17].

Introduction

As imaging improves, pancreatic cysts are being incidentally detected with increasing frequency. Older studies found a prevalence of 2.6% with computed tomography (CT) and 3–13% of magnetic resonance imaging (MRI) studies [1,2], with more recent studies identifying pancreatic cysts in 49% of patients undergoing MRI [3]. However, the size and morphology of these cysts determine management. Pancreatic cysts represent a range of etiologies from benign cysts such as pseudocysts or serous cystadenomas, those with the potential for progressing to invasive carcinoma (IC), such as intraductal papillary neoplasms (IPMN), and mucinous cystic neoplasms (MCN), as well as those associated with a high risk of IC such as solid pseudopapillary neoplasms (SPN) or cystic degeneration of a neuroendocrine tumor (NET). The four most common types of pancreatic cysts seen are pseudocysts, IPMN, MCN, and serous cystadenomas (SCA), which account for over 90% of pancreatic cysts seen [4].

Imaging plays two critical roles. First, to identify the type of cyst, and second, to identify features associated with the presence of high-grade dysplasia (HGD) or IC in patients with IPMN and MCN, in whom surgical resection should be considered [5,6]. In this chapter we review the imaging features of different types of pancreatic cysts using CT, MRI, and endoscopic ultrasound (EUS).

Low-Risk Pancreatic Cysts

Pseudocyst

Pancreatic pseudocysts are inflammatory collections related to trauma, acute or chronic pancreatitis. They are well defined, and found either within, or adjacent to the pancreas, and can be single or multiple. Initially the wall is thin but may thicken as the pseudocyst matures. Pseudocysts appear as low-attenuation fluid collections on CT. MRI provides improved soft tissue resolution and helps better assess the contents of the fluid collections and integrity of the pancreatic duct. On T1 weighted (T1W) images, pancreatic pseudocysts have a hypointense center, with an enhancing wall. On T2 weighted (T2W) images pseudocysts appear hyperintense due to their fluid content. Blood products, necrotic or proteinaceous debris are commonly present in postnecrotic collections associated with necrotizing pancreatitis (walled-off pancreatic necrosis) and are seen as areas of increased signal on T1W images [7]. Similarly areas of decreased signal may be seen in postnecrotic collections or walled-off pancreatic necrosis due to the presence of debris [7]. In acute pancreatitis, peripancreatic fluid and stranding may be present, which correlates with the degree of inflammation present on the T2W fat-suppressed images [8]. Furthermore, magnetic resonance pancreatography (MRCP) sequences help delineate pancreatic ductal disruption and/or communication with the fluid to guide treatment. Presence of gas within the collection may be due to superimposed infection or fistulous communication with the adjacent bowel. Infected collections may be better assessed on diffusion weighted imaging (DWI) with visualization of a hypointense rim on the apparent diffusion coefficient (ADC) map [9]. On EUS, they appear as a well-defined, anechoic lesion. The wall may appear thickened, and debris can appear as irregular, echogenic material within the cyst (Fig. 84.1). Differentiating pseudocysts from IPMN can occasionally be difficult, as highlighted by surgical series in which pseudocysts account for between 3% and 6% of resected cases, and cyst fluid analysis can be helpful in these cases [4,10]. A very low cyst fluid amylase of <250 U/L excludes 98% of pseudocysts [11]. A CEA of <5 ng/mL has a high specificity (98%), but low sensitivity (50%) for a pseudocyst [11].

Serous Cystadenoma

SCA are typically single cysts, and can occur in any location in the pancreas. The exception to this rule is von Hippel–Lindau disease, in which multiple SCA occur. Two-thirds occur in women, with a median age of presentation of 58 years [12]. They carry an exceptionally small risk (0.1%) of transformation into a cystadenocarcinoma [12]. Thus, differentiating these very low-risk cysts from other types of neoplastic cysts is extremely important for appropriate clinical management. Classical teaching is that SCA have a nondilated main pancreatic duct, which does not communicate with the cyst. Upstream dilation of the main pancreatic duct is an uncommon feature but may be seen due to mass effect [13]. The presence of a central scar, with or without calcification, is found in between 11% and 30% of SCA and is very specific [14]. A microcystic, or honeycomb, appearance is found in 45–58% of SCA, 32–35% have a macrocystic appearance, 18–28% a mixed macro or microcystic appearance, and 5–6% have a solid appearance (Fig. 84.2a–d) [12–14]. On

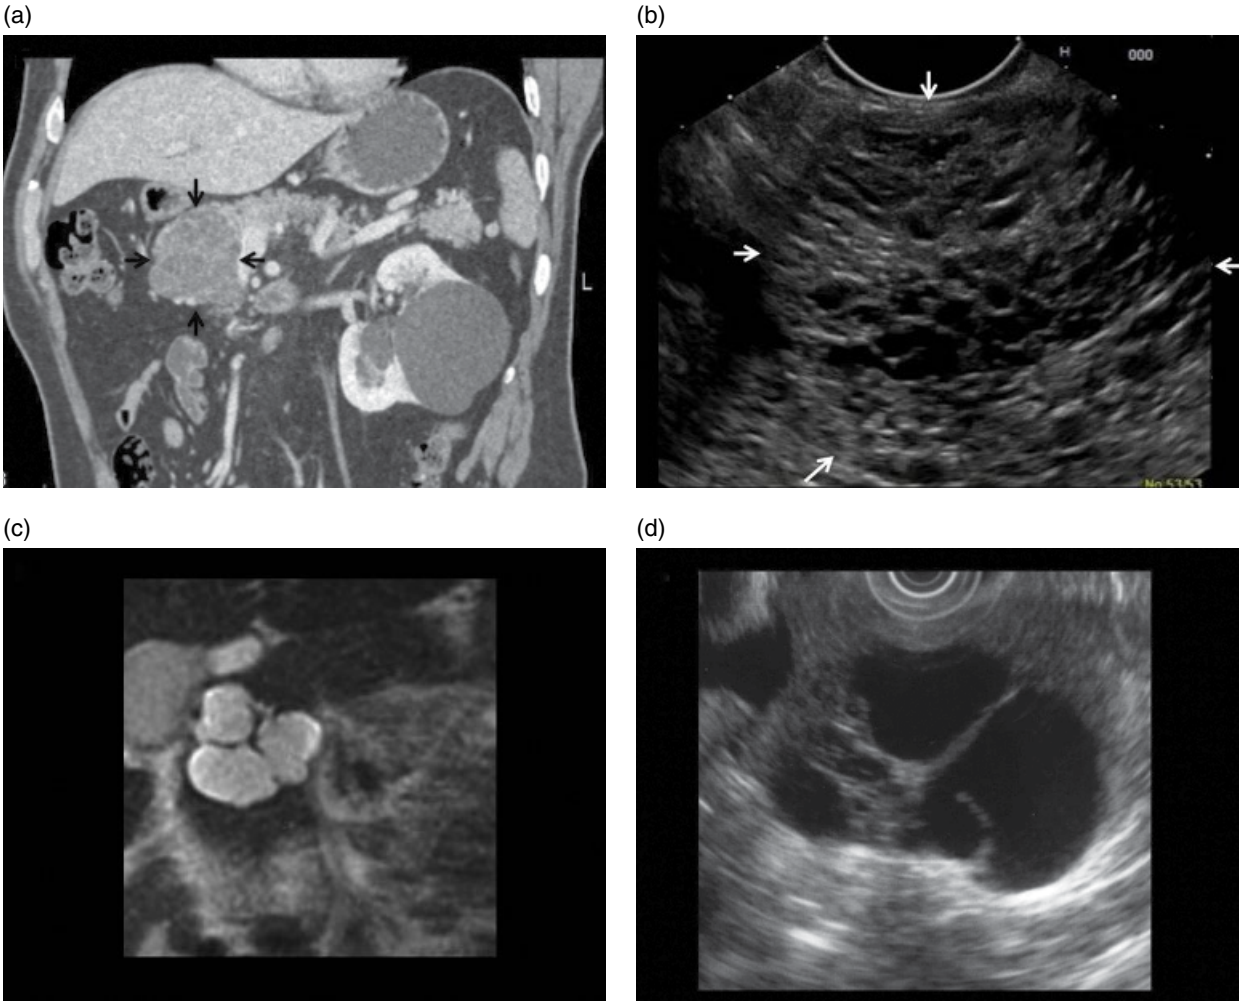

Figure 84.2 Serous cyst. Serous cysts (white arrows) have a range of appearances including microcystic (a, b), macrocystic (c), mixed macro and microcystic (d). They can occasionally have a solid appearance (e, f). In these cases MRI/MRCP is helpful in confirming the cystic, rather than solid nature of the cyst (g). *Source:* (a, b) Copyright AML, by permission of the author.

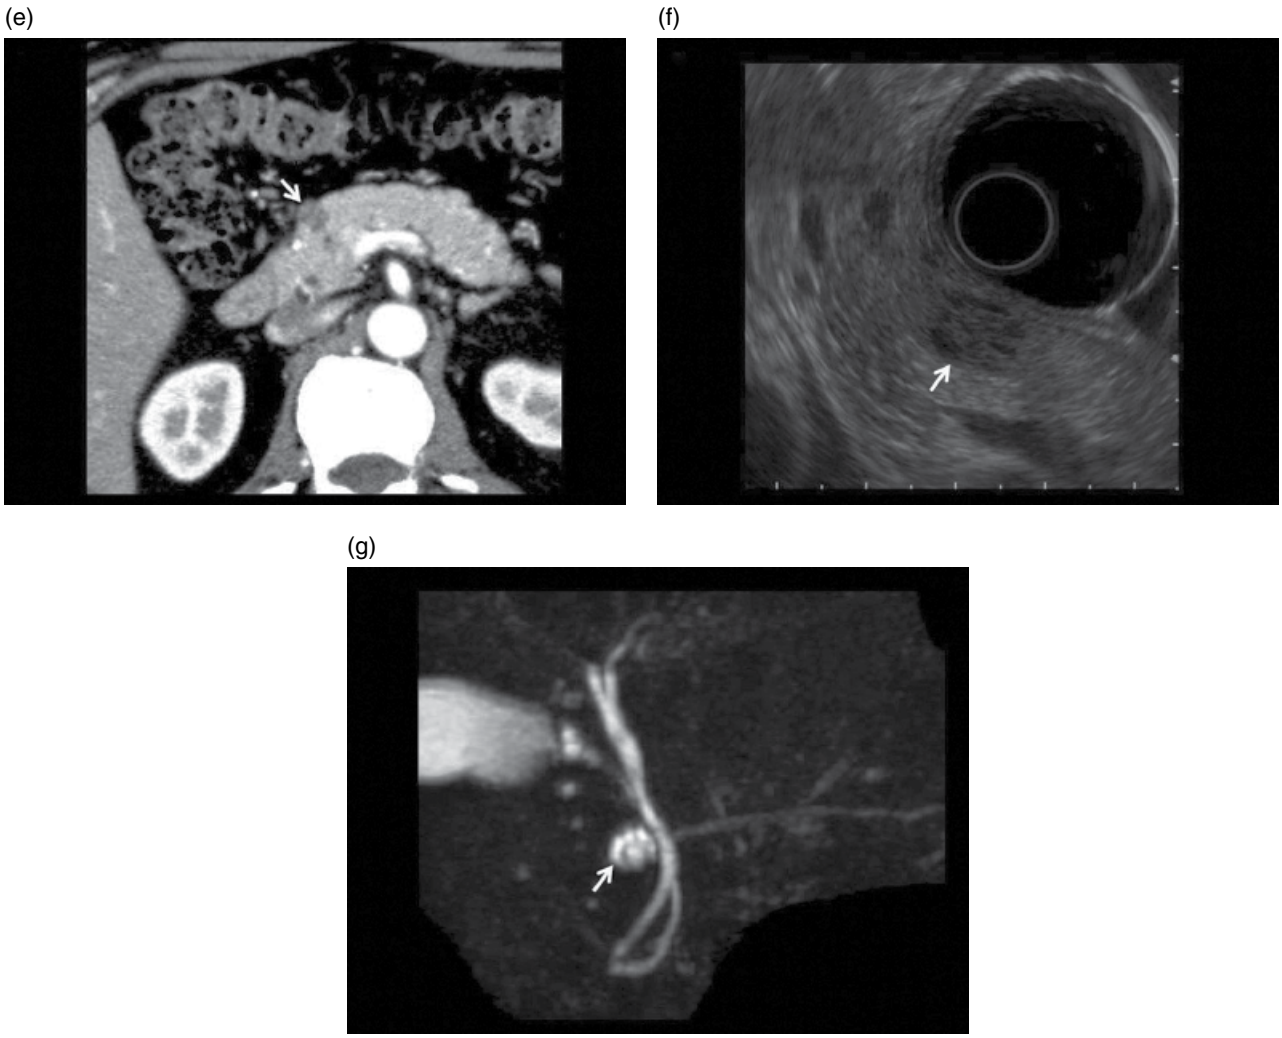

Figure 84.2 (Continued)

CT, the most common appearance is a lobulated conglomeration of small cysts that may exhibit a central scar with or without calcification [15]. The adjacent blood vessels may drape around the lesion and aggressive features such as invasion and vascular thrombosis are absent. On MRI they have a low intensity on T1W imaging, high signal on T2W imaging, with enhancement of the septations on contrast-enhanced T1W imaging with or without a central scar. In solid appearing SCA on CT, T2W imaging and MRCP is useful for confirming the cystic, rather than solid nature of the cyst (Fig. 84.2e–g). EUS can be useful in these cases in which classic imaging features are absent. It is superior for identifying a classic microcystic appearance to either CT or MRI [14], while the vascular nature of SCA is often seen with Doppler, or with contrast-enhanced EUS. A very low cyst fluid CEA, of <5 ng/mL, has 95% specificity, and 50% sensitivity for a SCA [11]. Almost 59% of SCA harbor a mutation in the Von Hippel–Lindau (*VHL*) gene or loss of heterozygosity (LOH) of chromosome 3 where the *VHL* gene is located [13]. The presence of a *VHL* mutation and the absence of mutations in *GNAS*, has 46% sensitivity and 100% specificity for SCA [13].

Lymphoepithelial Cyst

Lymphoepithelial cysts are rare, benign pancreatic cysts, which occur predominantly in middle-aged men (82%), with a mean age of presentation of 55 years [16]. They are single cysts, with almost 70% found adjacent, or outside of the pancreas [17]. Sixty percent are multilocular. The main pancreatic duct is normal, and unlike IPMN or pseudocysts, there is no communication between the cysts and the duct.

Lymphoepithelial cysts may have a mixed solid and cystic appearance, with a purely cystic or mainly solid lesion occurring in only 14% and 16% of cases, respectively (Fig. 84.3a, b) [16]. These cysts are low attenuation on CT and appear to abut the pancreatic parenchyma. On MRI, the lesions mostly appear hypointense on T1W, and hyperintense on T2W imaging. However, presence of

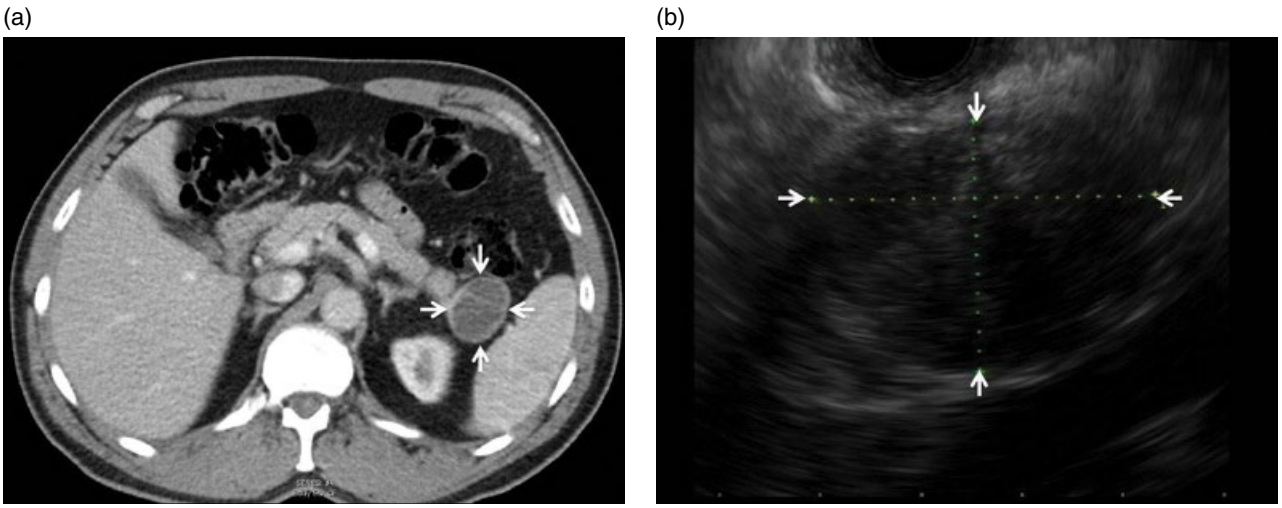

Figure 84.3 Lymphoepithelial cyst. The CT (a) and EUS (b) appearance. *Source:* Copyright AML, by permission of the author.

granular keratinized epithelium may cause them to appear high attenuation on CT, hyperintense on T1W imaging, and heterogeneous on T2W imaging due to the presence of fluid (high signal) and high keratin content (low signal) [16]. Furthermore, loss of signal on out of phase chemical shift imaging may be seen due to the presence of lipid content. These features are not classically seen in other cysts and may be helpful in identifying these lesions [16]. On EUS they are a solid-appearing, hypoechoic, heterogeneous lesion with posterior acoustic enhancement and may have evidence of debris within the cyst [17]. Cytology can be useful and identified 22% of lymphoepithelial cysts in a large series of 117 patients [16]. Cyst fluid CEA is >192 ng/mL in a third of patients [16].

Pancreatic Cysts with Malignant Potential

Mucinous Cystic Neoplasm

Mucinous cystic neoplasms (MCN) are single cysts, which occur almost exclusively in women (20:1 ratio), with a mean age of presentation of 53 years [18]. MCN are almost always located in the body or tail of the pancreas. Although MCN do not involve the main pancreatic duct, ductal abnormalities can be found. Main pancreatic duct dilation is found in up to 17% of MCN, which increases to 43% in the presence of HGD/IC. The absence of communication between the cyst and the main pancreatic duct is considered a classic feature used to differentiate MCN from IPMN [19]. Almost 40% of MCN are multilocular, and may have slightly thickened septations. The classic appearance of an MCN is a thickened wall which enhances on contrast-enhanced CT and MR imaging. This thick wall, or capsule, often has a "cyst within a cyst" appearance, which resembles an orange on CT or MRI (Fig. 84.4a, b). On EUS the cyst is unilocular with the "cyst within a cyst" seen within the wall (Fig. 84.4c). Calcification is located at the edge of the cyst creating an "eggshell" type appearance (Fig. 84.4d, e). In large surgical series between 15% and 25% of MCN have a mural nodule, increasing to 54–100% in MCN with HGD/IC [19,20]. This is seen on CT and MRI as intracystic enhancing soft tissue, or a hypoechoic, irregular area on EUS (Fig. 84.4f). Other features favoring malignancy include size >4 cm and thick irregular walls. Cyst fluid CEA (>192 ng/mL) and amylase are elevated. *KRAS* mutations are present in 35% of MCN [13].

Intraductal Papillary Mucinous Neoplasm

IPMN can involve the main pancreatic duct (MD-IPMN), branch duct (BD-IPMN), or both, in which case it is termed a mixed-type IPMN (Fig. 84.5a–c). This classification is important, as it determines the risk of malignant transformation, and the management of patients with IPMN. IPMN have an equal distribution in men and women, with a median age of presentation of 66 years [21]. They have a slight preponderance for the head of the pancreas, especially the uncinated process, but can occur anywhere. Over a third of individuals with IPMN have multiple cysts [21]. On imaging they may appear as a single or multiple small cystic lesions or as a cluster of small cysts with lobulated margins that appear as a "cluster of grapes." One of the classic features used to identify BD-IPMN is the presence of communication between the cyst and the main pancreatic duct (Fig. 84.5b). This is best assessed with MRI/MRCP, which have a very high reported sensitivity of 100% [22]. Cysts are usually well defined, with thin walls, can be unilocular or multilocular, and calcification is rarely present.

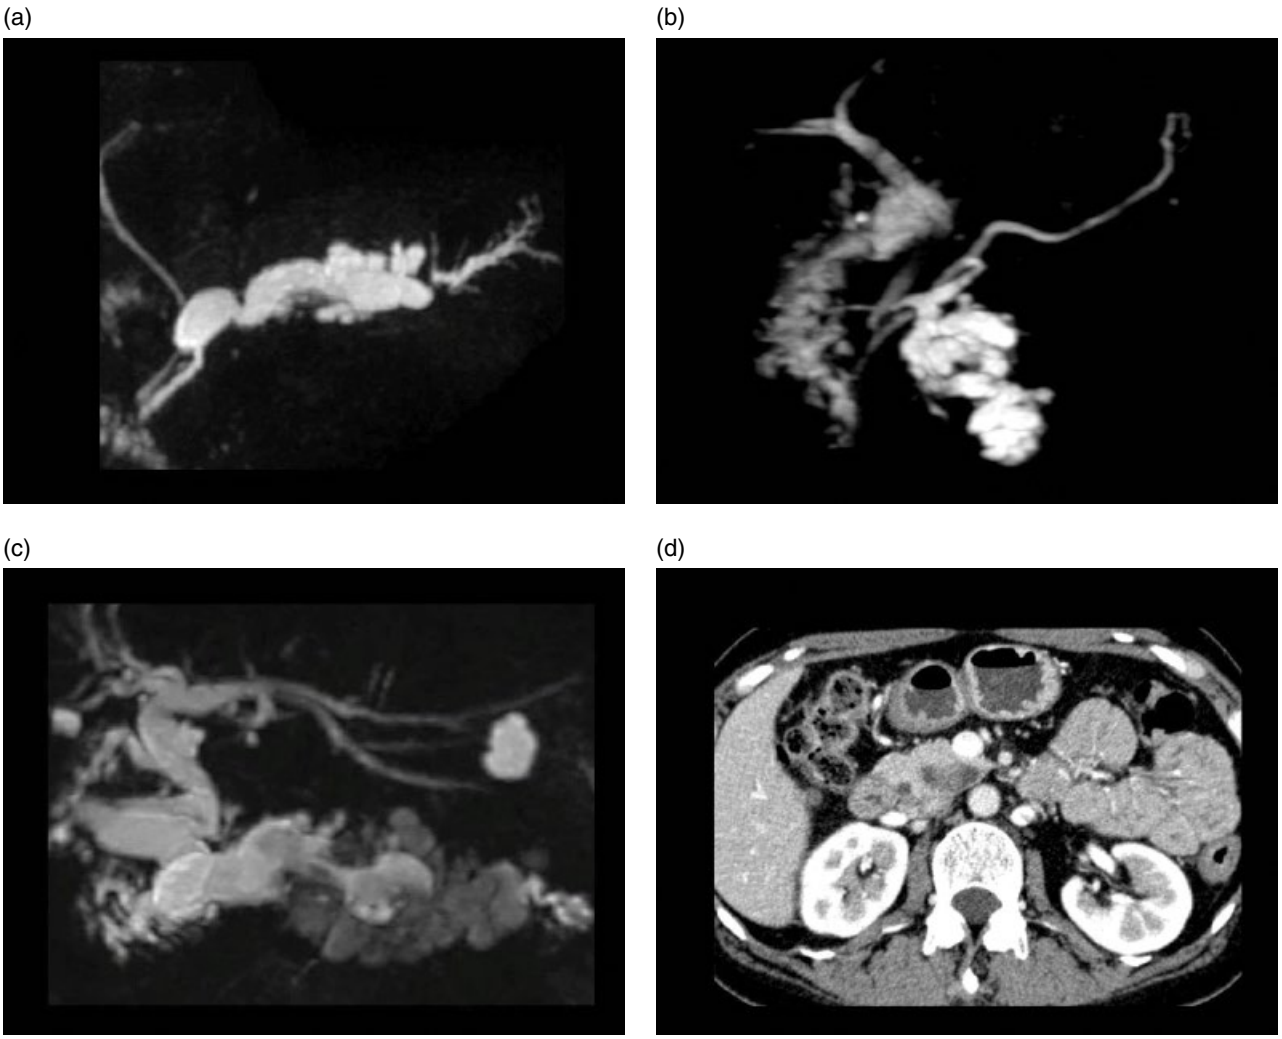

Figure 84.5 IPMN. The classic dilated main pancreatic duct seen in main-duct IPMN (a). In comparison there is a cyst but a normal pancreatic duct in a BD-IPMN (b, c), and a dilated main pancreatic duct and a cyst in a mixed-type IPMN (c). Mural nodules appear as soft tissue mass with contrast enhancement on CT and hyperechoic protruded lesion on EUS (d, e). Tissue harmonic echo (THE) shows a superior imaging compared with B-mode (f, g).

Main-duct involvement, which occurs in MD-IPMN or mixed IPMN, is defined as focal or diffuse dilation of the main pancreatic duct to >5 mm. They may appear cystic if only a short segment of the duct is involved. On endoscopy a gaping "fish-mouth" papilla extruding mucus is occasionally seen.

IPMN have the potential to progress to HGD or IC. There are a number of imaging features that are associated with an increased risk of HGD or IC including cyst size >3 cm (odds ratio [OR] 2.97), dilation of the main pancreatic duct (OR 2.4), and the presence of a solid component, or mural nodule (OR 7.7) [23]. Molecular marker evaluation of cyst fluid obtained at the time of EUS, is increasingly being used. The presence of a *TP53* or a *SMAD4* mutation is associated with an OR of 1.6 and 5.1, respectively, for the presence of HGD or IC [13], while another study found the presence of both a TP53 and PIK3CA mutation was associated with 79% sensitivity and 96% specificity for HGD or IC [24].

On CT and MRI a mural nodule appears as a soft tissue nodule protruding into mucin-filled dilated duct or cyst and shows enhancement following administration of intravenous contrast or as a hyperechoic, irregular lesion arising on EUS (Fig. 84.5d, e). The size of the mural nodule is associated with the risk of IC; however, the exact size is unclear and varies in studies from ≥3 mm to >10 mm, with the latter associated with IC in almost 90% of patients in one study [25,26]. Mucin appears as a hypoechoic lesion, with a hyperchoic, smooth rim on EUS, and is non-enhancing on CT or MRI. Contrast-enhanced EUS (CE-EUS) may demonstrate vascularity in mural nodules and is useful for differentiating a mural nodule from a mucin ball.

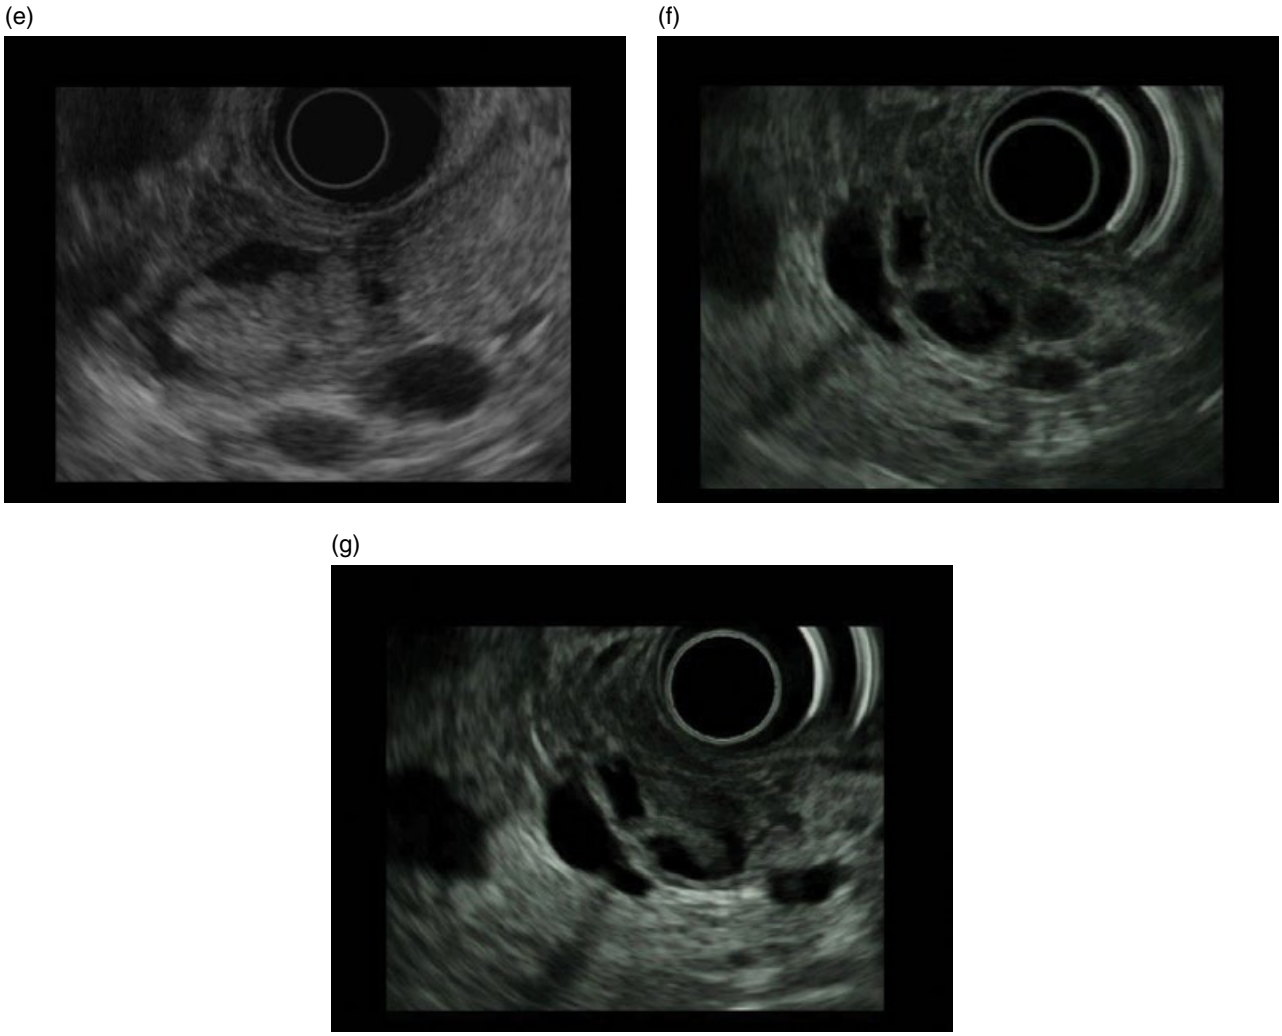

Figure 84.5 (Continued)

A prospective study found that CE-EUS correctly identified 75% of mural nodules with HGD or IC. Tissue harmonic echo (THE) imaging is a further development in EUS. Preliminary studies appear promising, and show superior image visualization of mural nodules compared with normal B-mode imaging (Fig. 84.5f, g) [27]. Individuals with IPMN can develop concomitant pancreatic adenocarcinoma in a region separate to the cyst, highlighting the importance of inspecting the entire parenchyma and not just the cyst. The cyst fluid analysis shows a high CEA (>192 ng/mL), and high amylase. The presence of either a *GNAS* or *KRAS* mutation has 85% to 100% sensitivity and 96% to 97% specificity for identifying an IPMN [13,24].

Solid Pseudopapillary Neoplasm

SPN are single cysts, with 60% located in the body or tail of the pancreas. Almost 90% occur in women, presenting at a mean age of 29 years [28]. The main pancreatic duct is normal, and does not communicate with the cyst. The cysts are well circumscribed, round or oval, with calcification present in almost half the cases [29]. In ~70% of cases, the imaging appearance is of a cystic and solid lesion, in 30% they are predominantly solid, and in rare cases are entirely cystic (Fig. 84.6a) [28,29]. The imaging appearance varies due to the cystic and solid nature of these neoplasms with areas of fluid appearing as low attenuation on CT and high signal intensity on T2W, and the solid components appearing higher attenuation on CT and mixed signal intensity on T2W imaging with weak enhancement within the solid components [30]. Areas of increased signal may be seen on the pre-contrast T1W imaging due the presence of hemorrhage within the lesions. A capsule with or without calcifications may also be present.

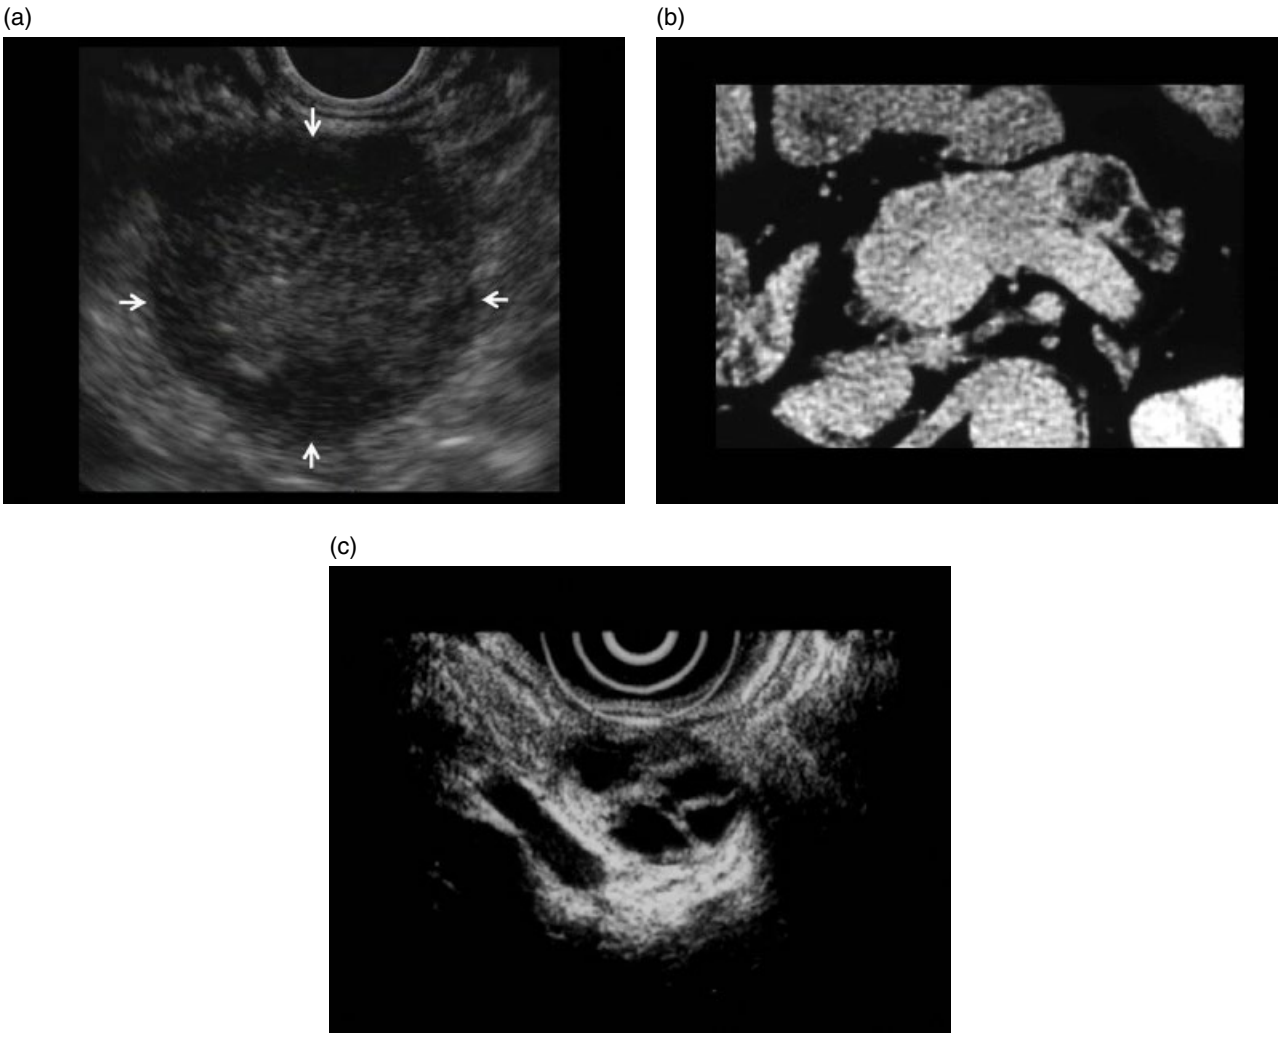

Figure 84.6 SPN and PanNET. Solid appearing SPN (a). Cystic PanNET showing enhancement of the rim and septum on CT (b). On EUS the appearance is of a solid component with cystic areas (c). *Source:* (a) Copyright AML, by permission of the author.

Cystic Neuroendocrine Tumor

Cystic degeneration of neuroendocrine tumors is rare, occurring in less than 20% of cases [31]. There is an equal distribution between genders, with a mean age at presentation of 53 years. These cysts are predominantly solid, with the cystic component due to degeneration of the tumor. They are round, usually well defined, with a rim of tissue that shows hyperenhancement on the arterial phase CT and MR imaging. Gallium 68–tetraazacyclododecane tetraacetic acid-octreotate PET/CT can help detect PNET with 93% sensitivity and 91% specificity and also helps in staging detection of recurrent and metastatic disease [32]. On EUS they appear as a well-defined, round, hypoechoic lesion, with an anechoic cystic area (Fig. 84.6b, c). They often have a vessel running around the edge of the lesion. Cyst fluid CEA and amylase levels are low.

Future Technology

In the field of medical imaging, recent work in radiomics has shown promising results in the diagnosis and risk stratification of the pancreatic cystic lesions, which utilizes extra information such as shape, texture, and grayness stored in various imaging modalities such as CT or MRI that is beyond human visual perception. Radiomic features have shown promising results in differentiating IPMN, MCN, and SCA with an accuracy, in one study, of up to 83.6%, and predicting IPMN with an accuracy of up to 96% using CT [33]. In another study, a combined model with radiomic and CT features outperformed the CT features alone in differentiating macrocystic SCA from MCN [34]. Some work has also been done to predict high-grade dysplasia or adenocarcinoma within IPMN with predictive nomograms diagnosing cancer

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. preoperatively. In one such study, a combination of multiple radiomic features with CA 19-9 levels and main pancreatic duct size helped predict high-grade disease with AUC of up to 0.876 [35]. The use of radiomic features as a tool for genetic profiling (radiogenomics) may further help improve high-risk patient characterization and outcome prediction. This is a rapidly evolving field, with clinical trials and research at big academic centers showing an immense potential in the accurate diagnosis and risk prediction of pancreatic cystic lesions.

Needle-based confocal endomicroscopy (nCLE) is a relatively new technology in which a very thin microscope is passed through a 19-gauge EUS-FNA needle into a cyst and creates a real-time optical biopsy of the cyst. Initial studies found that different types of cysts had specific imaging features, such as a superficial vascular network in SCA, or papillary projection in IPMN. To date there have been seven prospective trials enrolling between 18 and 144 patients and reporting a sensitivity of between 59% and 100%, and specificity of between 94% and 100% in differentiating IPMN from other types of pancreatic cysts [36–42], and is more accurate than cyst fluid CEA and cytology. One limitation is that almost all the studies are in patients with a large cyst of at least 2 cm in diameter and this technique is probably not applicable to smaller cysts.

Cytologic Evaluation of Cystic Neoplasms: The Role of Liquid Biopsy

Abdulwahab Ewaz and Michelle D. Reid

Department of Pathology, Emory University Hospital, Atlanta, GA, USA

Introduction

In the era of highly sensitive imaging modalities, most pancreatic cystic lesions (PCL) are incidentally discovered during screening for unrelated presentations. Detection rates range from 2.4% to 49.1%, creating a major management problem, requiring noninvasive diagnostic tests to stratify risk and management [1,2].

Endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) or liquid biopsy is frequently used to sample pancreatic lesions. It shows variable sensitivity (60–96%) but high specificity in diagnosis [3,4]. However, when assessing PCL, EUS-FNA performance is significantly challenged. Accurate diagnosis of PCL requires integration of clinical and radiologic information, biochemical and molecular analysis of cyst fluid, and cytology.

Types of Pancreatic Cystic Lesions

Pancreatic cysts are either nonneoplastic or neoplastic. Most nonneoplastic PCL arise secondary to postinflammatory sequelae of acute and/or chronic pancreatitis, and include pseudocysts (the most frequently encountered [75%] nonneoplastic PCL), paraduodenal cysts, lymphoepithelial cysts (LEC), and squamoid cysts of pancreatic duct (SCOPD). Neoplastic cysts are low-risk (serous cystadenoma) or high-risk (mucinous and nonmucinous cystic/intraductal lesions, solid pseudopapillary neoplasm [SPN]). Intraductal papillary mucinous neoplasm (IPMN) and mucinous cystic neoplasm (MCN) constitute the majority of neoplastic PCL. Other nonmucinous cystic intraductal lesions include intraductal oncocytic papillary neoplasm (IOPN) and intraductal tubulopapillary neoplasm (ITPN) [5,6]. Serous cystadenoma (SCA) and SPN are nonmucinous, nonductal cystic neoplasms. Solid pancreatic tumors (ductal adenocarcinoma, neuroendocrine neoplasms, and acinar cell carcinoma) may undergo cystic degeneration and should be considered in the differential.

Reporting Terminology for Pancreatobiliary Cytology Specimens

In 2014, the Papanicolaou Society of Cytopathology (PSC) proposed standardized reporting for pancreatobiliary cytology [7]. This includes six categories: I. Nondiagnostic, II. Negative, III. Atypical, IV. Neoplastic (benign or other), V. Suspicious, and VI. Positive for malignancy. Nonneoplastic pancreatic cysts are classified as negative. Serous cysts are "neoplastic: benign," while mucinous/intraductal nonmucinous cysts (IPMN, MCN, IOPN, and ITPN) and SPN are in the "neoplastic: *other*" category. Cystically degenerated ductal adenocarcinoma and acinar cell carcinoma are malignant (see Table 85.1). Risk of malignancy (ROM) increases with each category (7.7% for nondiagnostic; 1% for negative; 28% for atypical; 0% for neoplastic: *benign*; 30.3% for neoplastic: *other*; 90.0% for neoplastic: *other* with high-grade atypia [HGA]; to 100% for suspicious; and 100% for positive) [8].

Assessment of Pancreatic Cystic Lesions: A Multimodal Approach

The primary goal of preoperative assessment of PCL is to exclude malignancy, and then to distinguish low-risk from high-risk cysts. An integrated, multidisciplinary approach that incorporates clinical, radiologic, and

Table 85.1 Cytologic terminology and reporting system of pancreatic cystic lesions.

Diagnostic category	Diagnostic entity
Negative	Pseudocyst Paraduodenal cyst of groove pancreatitis Lymphoepithelial cyst (LEC) Squamoid cyst of pancreatic duct (SCOPD)
Neoplastic: Benign	Serous cystadenoma
Neoplastic: Other	Intraductal papillary mucinous neoplasm (IPMN) Mucinous cystic neoplasm (MCN) Intraductal oncocytic papillary neoplasm (IOPN) Intraductal tubulopapillary neoplasm (ITPN) Pancreatic neuroendocrine tumor (PanNET) Solid pseudopapillary neoplasm (SPN)
Positive/ Malignant	Solid malignancy with cystic degeneration • Adenocarcinoma • Lymphoma • Sarcoma • Metastatic malignancies • Neuroendocrine carcinoma • Acinar cell carcinoma

cytologic findings with (chemical/molecular) cyst fluid analysis and ancillary studies, is necessary to ensure accurate preoperative classification [9].

Radiologic and Clinical Assessment

Detailed radiologic assessment of PCL is beyond the scope of this text. However, some radiologic and clinical findings should prompt consideration of specific entities. For middle-aged patients with a single or multiple PCL involving the main and/or branch pancreatic ducts and associated with leakage of thick mucin from the ampulla of Vater, the main differential is IPMN. This contrasts with MCN, SCA, LEC, pseudocysts, paraduodenal/groove cysts, and SPN, which do not involve pancreatic ducts. For perimenopausal/postmenopausal females with multilocular tail cysts the main differential is MCN. In elderly females with circumscribed multiloculated cysts, an associated central stellate scar and no duct involvement, the main differential is SCA. For young females in the second to third decade with tail cysts, SPN is the main differential.

Use of Rapid Onsite Evaluation (ROSE) in the Analysis of Pancreatic Cysts

During rapid onsite evaluation (ROSE) a cytopathologist can assess cyst viscosity, which in mucinous cysts is greater than that of serum [10]. Mucinous cysts yield thick, mucoid material that is difficult to express from needles. Nonmucinous cysts only rarely show high viscosity. Use of ROSE in cytologic evaluation of PCL risks wasting limited fluid that should be prioritized for carcinoembryonic antigen (CEA) and amylase quantification, and molecular studies. ROSE can be used to assess a solid component in IPMN or MCN.

Biochemical Analysis of Pancreatic Cyst Fluid

Measurement of cyst fluid CEA is the mainstay of biochemical analysis of PCL. It requires approximately 0.5 mL of fluid and has a higher sensitivity, specificity, and accuracy than cytology or EUS-FNA alone [11]. Values of 192 ng/mL and higher (range 110–200 ng/mL) have high accuracy (80%), sensitivity (75%), and specificity (84%) for mucinous cysts [11]. Lower values do not completely exclude mucinous cysts, and individual laboratories must establish thresholds. CEA alone cannot distinguish IPMN from MCN, nor identify malignant mucinous cysts [12]. CEA is rarely elevated in nonmucinous cysts (pseudocysts, SCOPD, SCA, LEC), and should not be interpreted in isolation [11,12].

Cyst fluid amylase can distinguish pseudocysts and mucinous cysts (IPMN and MCN) from SCA, which typically has low amylase. Pseudocysts have the highest amylase (>1000 ng/mL) but low CEA levels. In fact, an amylase level below 250 U/L excludes a pseudocyst [12]. High amylase plus high CEA favors IPMN or MCN, but cannot distinguish between them [13].

Vascular endothelial growth factor-A (VEGF-A) has high sensitivity (100%) and specificity (97%) for SCA and is incomparably higher in SCA than pseudocysts, IPMN, and MCN [14]. Cyst fluid glucose <50 mg/dL is more sensitive than CEA >192 ng/mL (93.6% vs. 54.8%; $P = 0.003$) in diagnosing mucinous cysts, but with similar specificity (96% vs. 100%; $P = 1$) [15].

Molecular Analysis of Pancreatic Cyst Fluid

Different cyst types have specific molecular alterations that show high concordance with resection [16,17]. *VHL* mutations have been identified in SCA cyst fluid, while *KRAS* mutations and loss-of-heterozygosity (LOH) in tumor suppressor genes *CDK2NA*, *RNF43*, *SMAD4*, and *TP53* have been identified in mucinous cysts and distinguishes them from nonmucinous cysts [13,16–19]. Aneuploidy in mucinous cysts is linked to malignant transformation [13,16,17,20]. *PRKACA* and *PRKACB* fusions are seen in cyst fluid of pancreatic/biliary IOPN and their invasive counterparts [21]. Molecular alterations in specific cyst types are discussed in detail below.

Cytologic Analysis of Pancreatic Cyst Fluid

The primary goal of cytologic assessment of PCL is to identify malignancy and distinguish innocuous neoplastic and nonneoplastic cysts from high-risk cysts prone to harboring or progressing to carcinoma. Low-risk cysts are typically only resected if patients are symptomatic or definitive cytologic or imaging diagnosis is impossible. In contrast, because high-risk cysts have a high risk of harboring carcinoma they should ideally be resected in suitable surgical candidates. Resection of high-risk cysts depends on clinical confounders, cyst size, pancreatic duct diameter, mural nodule, and cytologic and/or molecular findings suggestive of malignancy [22].

Mucinous Pancreatic Cysts

Mucinous pancreatic cysts include MCN and IPMN, which are lined by mucin-producing epithelium with villi formation, variable cytoplasmic mucin, and a spectrum of dysplasia (low- or high grade). Some harbor invasive ductal adenocarcinoma (approximately 30% of IPMN and 17% of MCN).

IPMN accounts for 3–5% of all pancreatic tumors and comprises ~40% of all resected primary pancreatic cystic neoplasms. IPMN tend to affect older males (mean age 68 years) and the majority involve the head. IPMN cysts are larger than 1.0 cm and arise from, and involve, main and/or branch ducts. There are three epithelial subtypes: gastric, intestinal, and pancreatobiliary. Gastric-type IPMN has villi lined by gastric-type epithelium that is often low grade. Intestinal-type IPMN forms larger, complex cystic lesions and morphologically resembles colonic villous adenoma. Invasive carcinoma is seen in a third of intestinal-type IPMN and is most frequently colloid type. Pancreatobiliary-type IPMN has villi that are lined by cuboidal or columnar cells with high-grade dysplasia.

In contrast, MCN is a mucin-producing cyst that does not involve the duct system, and is defined by ovarian-type stroma (OTS) in its wall. OTS has all the features of ovarian cortex and expresses estrogen and progesterone receptors. MCN occurs almost exclusively (>97%) in the tail/body of perimenopausal women (mean age 48 years) and presents as multilocular cysts [23]. Invasive carcinoma is seen in approximately 17%.

Preoperative assessment of suspected mucinous cysts is used to identify high-grade cytologic atypia (encompassing high-grade dysplasia and/or invasive carcinoma). This is based on clinical information, imaging, cytology, and biochemical and molecular analysis of cyst fluid. The 2017 revised international consensus Fukuoka guidelines for IPMN management define "high-risk" stigmata (worrisome for, or supportive of, malignancy) as an associated solid component, main pancreatic duct diameter ≥10 mm, cyst size >= 3 cm (with thick walls/mural nodules), main duct size 5–9 mm (a worrisome feature), suspicious or positive cytology, and abrupt pancreatic duct caliber change with distal atrophy, among others [22]. If worrisome features are present, EUS-guided cytology is recommended and if "*neoplastic with high-grade atypia, or suspicious/positive for malignancy*" then surgery is recommended [24].

Cytologic Findings in Neoplastic Mucinous Cysts

Because the entity-defining OTS of MCN is rarely sampled on FNA, cytologic distinction between IPMN and MCN is practically impossible. In fact, the cytologic findings in IPMN and MCN are essentially identical, hence their combined classification under the umbrella term "neoplastic mucinous cyst." Aspirates from neoplastic mucinous cysts yield abundant thick, ropey colloid-like mucin in a background of neoplastic mucinous epithelium. Viscous mucin is magenta on Diff Quik and greenish-pink to orange on Papanicolaou stain (Fig. 85.1). Aspirates contain flat/folded/branching sheets, papillae, and clusters of mucinous cells (Figs 85.1 and 85.2). Less complex mucinous cysts may yield only thick acellular mucin, which in the appropriate clinical/radiologic setting, is diagnostic of a neoplastic mucinous cyst, if associated with elevated CEA.

Neoplastic cells in neoplastic mucinous cysts have well-defined cell walls (Figs 85.1 and 85.2). Gastric-type IPMN resembles normal gastric epithelium, intestinal-type resembles intestinal epithelium, and pancreatobiliary-type resembles pancreatobiliary adenocarcinoma (Figs 85.1 and 85.2). Gastric-type IPMN shows branching sheets and papillae comprised of cells with abundant cytoplasmic mucin (Fig. 85.1), and may be impossible to distinguish from normal gastric epithelium, which is usually sampled as the endoscopic needle traverses the gastric wall during aspiration of pancreatic body/tail lesions. Gastric foveolar epithelium typically contains U-shaped cytoplasmic mucin cups that fill the superficial third of the cell (Fig. 85.3). Gastric-type IPMN with low-grade atypia can be distinguished from gastric epithelial contaminants by correlating with cyst fluid CEA and amylase levels, which are elevated in IPMN and normal/low in gastric epithelial contaminants. If CEA and amylase are unavailable/inconclusive, then a diagnosis of "*Atypical findings. See comment*" is recommended with a comment stating that "If truly aspirated from a cyst, then this may represent a gastric-type IPMN." Other contaminants in EUS-FNA include watery extracellular GI tract mucin, and duodenal epithelium, which is usually sampled when the needle traverses the duodenal wall during sampling of pancreatic head/uncinate process cysts. Duodenal epithelium forms sheets of enterocytes and goblet cells, the nuclei of which are surrounded by a halo of mucin-rich cytoplasm (Fig. 85.3). Intestinal-type IPMN yields papillae

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 85.1 Neoplastic mucinous cyst. (a) Thick colloid-like ropey magenta-colored mucin in smear background (Diff Quik stain, 40×). (b) Neoplastic mucinous cyst with low-grade atypia has sheets of neoplastic columnar cells with low nuclear-to-cytoplasmic ratio, well-defined cell borders, pink cytoplasmic mucin, and rounded nuclei (Papanicolaou, 400×). (c) Neoplastic mucinous cyst with high-grade atypia has papilla (upper half of image) with central fibrovascular core and sheet of neoplastic cells (lower half of image) with high nuclear-to-cytoplasmic ratio and irregular hyperchromatic nuclei (Papanicolaou, 400×). (d) Cell block from part (c) shows multiple papillae lined by pseudostratified pancreatobiliary epithelium (H&E, 200×).

covered by pseudostratified columnar cells, with pencillate nuclei. Tumor cells are positive for intestinal markers MUC2, CDX2, and CK20. Pancreatobiliary-type IPMN show high-grade cytology (3-dimensional clusters and papillae with overlapping high nuclear-to-cytoplasmic ratio cells) and positivity for MUC1 (Fig. 85.2). Aspirates of MCN contain mucinous epithelial cells with variable atypia, in thick background mucin (Fig. 85.1).

Grading of Atypia in Neoplastic Mucinous Cysts (IPMN and MCN)

A 2-tiered classification system (low- vs. high-grade dysplasia) was proposed for precursor pancreatobiliary lesions IPMN, MCN, and pancreatic intraepithelial neoplasia (PanIN) [25]. Mild to moderate/intermediate dysplasia is classified as low grade, while severe dysplasia/carcinoma-in-situ is considered high grade, has a strong association with invasion, and warrants intervention [25]. In neoplastic mucinous cysts with low-grade atypia (equivalent to low-grade dysplasia) mucinous epithelium is bland, has a low nuclear-to-cytoplasmic ratio, polarized nuclei, even chromatin and inconspicuous nucleoli (Fig. 85.1). Gastric-type IPMN are usually low grade.

The cytologic term "high-grade atypia" in neoplastic mucinous cysts encompasses both high-grade dysplasia and invasive adenocarcinoma since cytology material typically lacks the required stromal component necessary to assess invasion [7,26]. Cytologic features of high-grade atypia include crowded or drunken honeycomb sheets, papillae, and 3-dimensional clusters of high nuclear-to-cytoplasmic

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

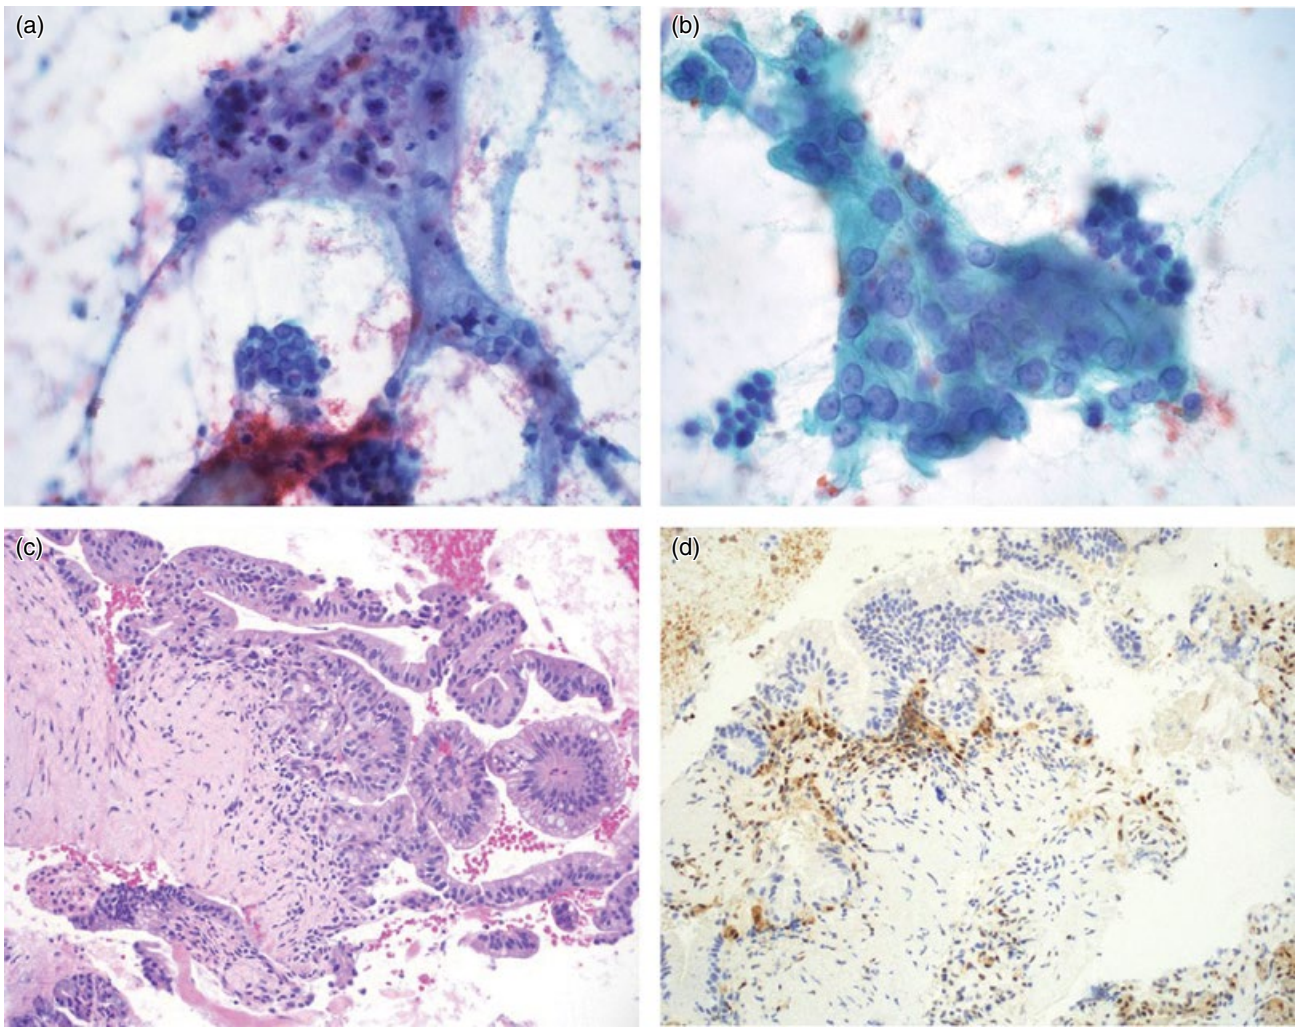

Figure 85.2 Neoplastic mucinous cyst with high-grade atypia. (a) Clusters of oncotic and high nuclear-to-cytoplasmic ratio cells in ropey mucin (Papanicolaou, 400×). (b) Neoplastic cells have high nuclear-to-cytoplasmic ratio, pale chromatin, and irregular nuclei (Papanicolaou, 400×). (c) Corresponding cell block shows cyst's fibrous wall lined by fused papillae covered by pancreatobiliary epithelium (Papanicolaou, 400×). (d) Papillae show SMAD4 loss (positive internal control in stromal cells).

ratio cells with irregular nuclei, change in chromatin (hyperchromasia and/or hypochromasia) and prominent nucleoli (Figs 85.1 and 85.2). Single high nuclear-to-cytoplasmic ratio cells, rounded cytoplasmic mucin vacuoles (Figs 85.1 and 85.2), and single cell or coagulative necrosis may also be seen (Fig. 85.2). By definition, pancreatobiliary-type IPMN is high grade, while intestinal-type IPMN may show low- or high-grade atypia (Fig. 85.2).

Immunohistochemical markers that can potentially identify high-grade cytologic atypia include placental S100 (S100P), insulin-like growth factor II messenger RNA binding protein-3 (IMP-3), and pVHL (von Hippel–Lindau protein). IMP-3 and S100P show nuclear and cytoplasmic positivity in high-grade atypia, while pVHL is negative and SMAD4 (an immunohistochemical surrogate for *SMAD4/DPC4* mutation) is lost (Fig. 85.2) [27].

Molecular Alterations in Neoplastic Mucinous Cysts (IPMN and MCN)

More than 90% of IPMN have either *GNAS* or *KRAS* mutations, and almost half show both [17,28]. *KRAS* mutation has a sensitivity and specificity of 54% and 100%, respectively, for ductal adenocarcinoma, IPMN, and MCN [18,29]. *GNAS* mutations are seen in up to 60% of IPMN, with intestinal-type showing the highest prevalence [17]. Somatic *RNF43* mutations are also seen in IPMN and MCN [18,28]. A commercially available molecular kit used to assess *KRAS* mutation, LOH, DNA quality, and DNA quantity in PCL had 83% sensitivity and 100% specificity for malignancy [30]. Other PDAC-related driver gene mutations (*TP53*, *p16/CDKN2A*, *SMAD4/DPC4*) may occur in IPMN and MCN, particularly those with high-grade dysplasia or invasion [13].

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

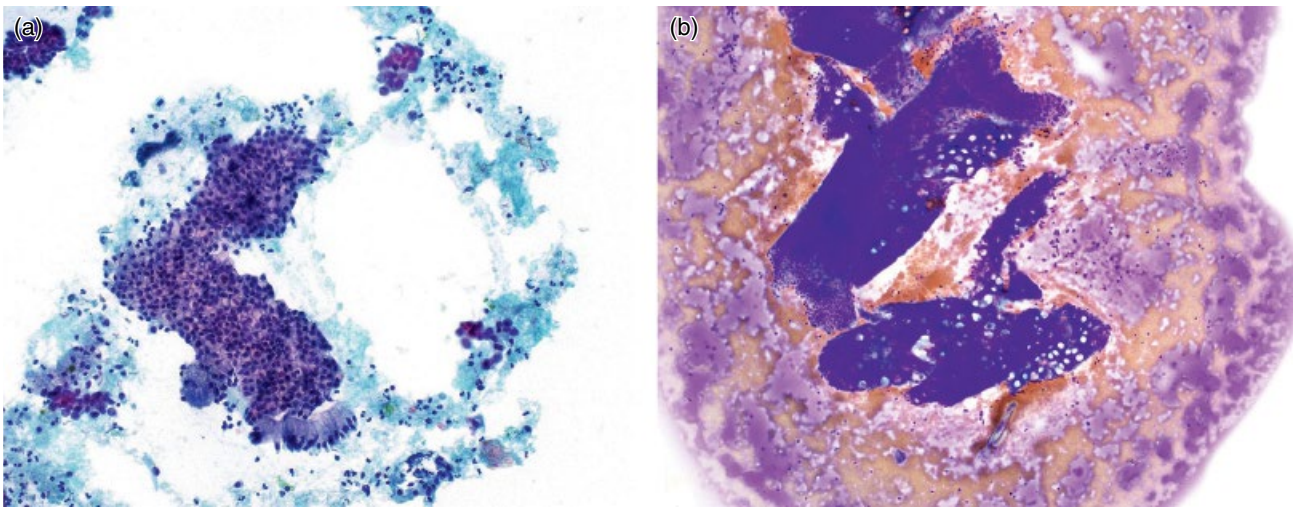

Figure 85.3 (a) Gastric epithelium with low nuclear-to-cytoplasmic ratio, basal bland nuclei (Papanicolaou, 40×). (b) Normal duodenal epithelium has small enterocytes and pale goblet cells. Note watery background gastrointestional tract mucin (Diff Quik, 200×).

Intraductal Oncocytic Papillary Neoplasm (IOPN)

IOPN is a cystic intraductal mucin-depleted tumor of the pancreatic/bile ducts [5,31]. IOPN was formerly considered as an IPMN subtype but is now classified separately [5,31,32]. Cysts are lined by complex branching or fused papillae covered by pseudostratified, multilayered oncocytic epithelium with brisk mitoses and oval or slightly irregular vesicular nuclei, and prominent macronucleoli. IOPN has an excellent prognosis with 10-year survival of over 95%.

The cytologic features of IOPN are quite distinctive [33]. Aspirates are usually hypercellular but background mucin is usually scant. Architecturally complex sheets and papillae are seen, lined by large, polygonal cells with low nuclear-to-cytoplasmic ratios, distinct cell membranes, dense granular eosinophilic cytoplasm, round or slightly irregular nuclei with vesicular chromatin and slightly eccentric, prominent nucleoli (Fig. 85.4). Cell blocks show papillae with edematous and/or hyalinized cores lined by two to five layers of pseudostratified oncocytic cells with interspersed rounded spaces, and scant mucin. Atypical mitoses and necrosis may also be seen. By definition, IOPN are high grade and are classified in the "neoplastic: *other*" category of the Papanicolaou Society cytologic guidelines (Table 85.1) [31].

IOPN is positive for MUC6, MUC5AC, and MUC1 and negative for MUC2, CK20, and CDX2. Unique molecular alterations were recently identified including *PRKACA* and *PRKACB* fusions (*DNAJB1-* and *ATP1B1-PRKACA*) [32]. IOPN may express the hepatocellular marker HepPar, but arginase is negative.

The differential diagnosis of IOPN includes pancreatic neuroendocrine tumors (PanNET), particularly oncocytic PanNET, and acinar cell carcinoma. Oncocytic PanNET have abundant granular oncocytic cytoplasm and may contain papillae resembling IOPN [34]. However, the eccentric nuclei, salt-and-pepper chromatin, and neuroendocrine marker expression should facilitate diagnosis of PanNET. Acinar cell carcinoma also shows abundant granular cytoplasm and oval nuclei with macronucleoli resembling IOPN. Unlike IOPN, acinar cell carcinoma expresses trypsin, chymotrypsin, and BCL10 [35].

Intraductal Tubulopapillary Neoplasm (ITPN)

ITPN is a relatively rare (<2%) complex, cystic or partially solid intraductal neoplasm of the pancreatic or bile duct. It forms polypoid intraductal neoplasms with back-to-back tubules, minimal papillae and no mucin production [6]. Tubules are lined by mucin-depleted cuboidal cells with high-grade cytology. Invasive pancreatobiliary tubular type carcinoma is common (~70%) [6].

Cytologic preparations of ITPN are composed of branching sheets or clustered mucin-depleted cells with high-grade cytology. Back-to-back tubules may also be seen (Fig. 85.4). Mitoses and necrosis are frequent but cytoplasmic/extracellular mucin is typically absent [9,36,37]. On cell block tubules may contain luminal mucin or proteinaceous eosinophilic concretions resembling enzymatic concretions of acinar cell carcinoma.

Tumor cells are positive for CK7, CK19, MUC1, and MUC6, and negative for MUC2 and MUC5AC. ITPN

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

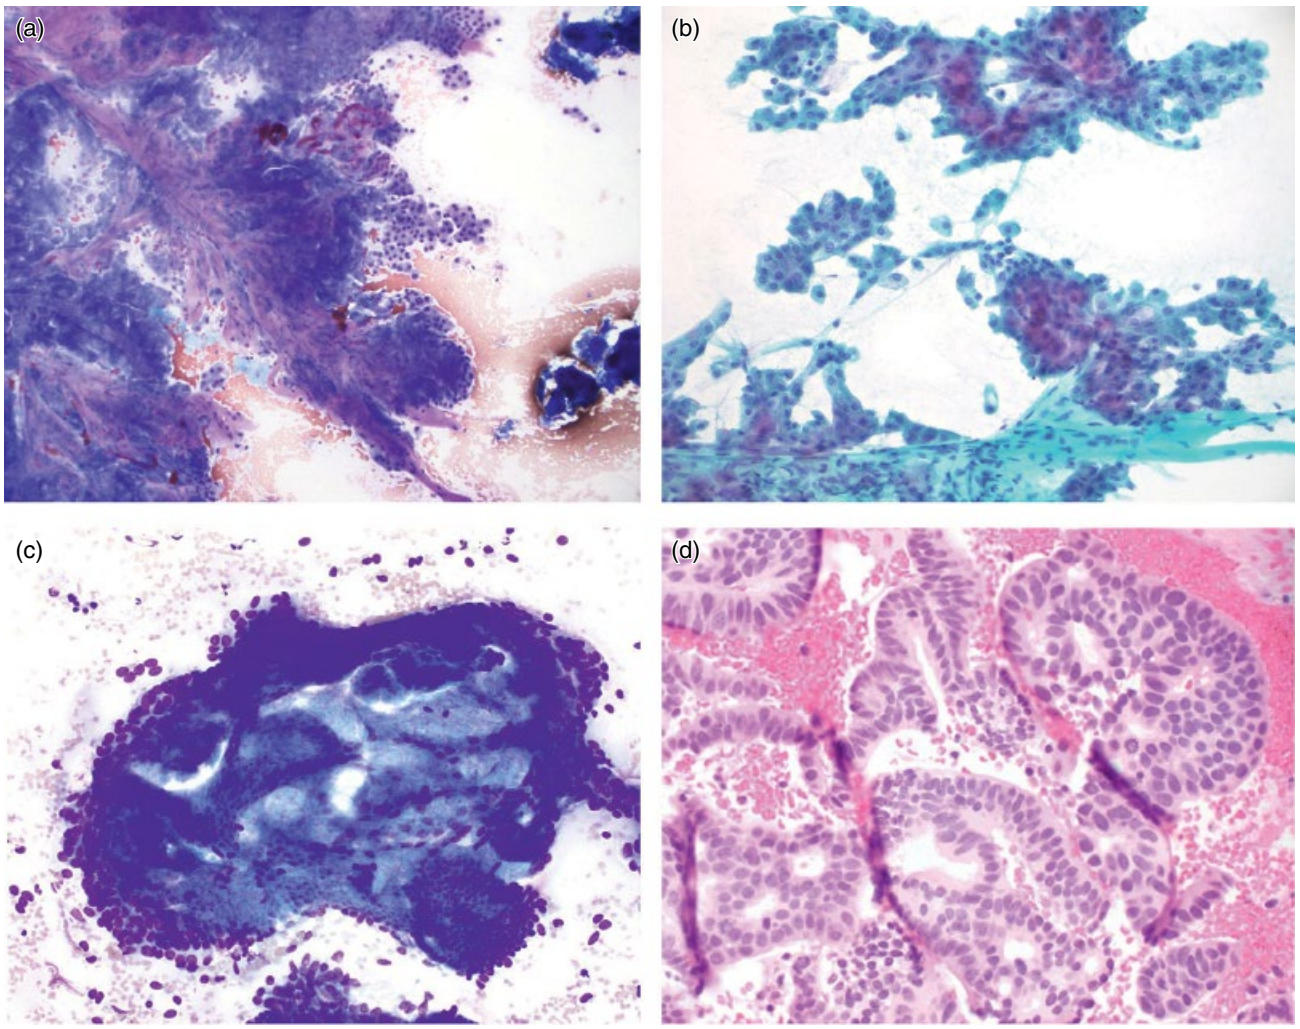

Figure 85.4 (a–b) Intraductal oncocytic papillary neoplasm (IOPN). (a) Hypercellular smear with magenta-colored broad fibrovascular cores (Diff Quik, 200×). (b) Branching papillae covered by oncocytic cells with abundant granular cytoplasm, low nuclear-to-cytoplasmic ratio and oval nuclei with vesicular chromatin and prominent nucleoli (Papanicolaou, 400×). (c–d) Intraductal tubulopapillary neoplasm (ITPN). (c) Crowded sheets of back-to-back tubules (Diff Quik, 200×). (d) Cell block from same case shows fused back-to-back tubules lined by pancreatobiliary epithelium with high nuclear-to-cytoplasmic ratio, no cytoplasmic mucin, and occasional abnormal mitoses (H&E, 400×).

may show phosphatidylinositol 3-kinase (*PIK3CA*) mutation, a potential diagnostic and therapeutic target. *P16/CDKN2A* mutations may also be seen.

Differential diagnosis for ITPN includes neoplastic mucinous cysts with high-grade atypia (particularly pancreatobiliary-type IPMN) and acinar cell carcinoma. Neoplastic mucinous cysts usually have cytoplasmic mucin and lack the back-to-back cribriform tubules of ITPN. Acinar cell carcinomas may be cystic/intraductal and have tumor cells containing dense granular cytoplasm with red zymogen granules, large nuclei and cherry-red nucleoli, reminiscent of ITPN. However, unlike ITPN, acinar cell carcinoma is positive for trypsin, chymotrypsin, and BCL10 [35].

NONMUCINOUS CYSTIC NEOPLASMS OF PANCREAS

Serous Cystadenoma (SCA)

SCA is a benign nonmucinous tumor of centroacinar cells and the second most common cystic pancreatic neoplasm. It predominantly occurs in elderly females (70%), frequently involves the body/tail and resection is curative [38]. Radiologically, SCA form sponge-like microcystic masses with a soap-bubble appearance. Oligocystic/unicystic variants may be misdiagnosed as IPMN or MCN. SCA often have high VEGF-A [14], but viscosity, CEA, and amylase levels are usually low [11].

SCA aspirates are predominantly bloody and hypocellular, with scant hemorrhagic/serosanguinous fluid, scattered hemosiderin-laden macrophages, stromal fragments and only rare tumor cells (Fig. 85.5). Tumor cells are bland with PAS-positive glycogen-rich clear cytoplasm, distinct cell membranes, and oval hyperchromatic nuclei [39].

SCA tumor cells are positive for pancytokeratin, PAS (with diastase digestion), inhibin, and glucose uptake and transporter-1 (GLUT1) (Fig. 85.5) [38]. *VHL* mutations and chromosome 3p aneuploidy have been reported in SCA cyst fluid [17].

Solid Pseudopapillary Neoplasm (SPN)

SPN are rare pancreatic tumors that arise in the pancreatic tail of young women in the third decade. Tumors present as large (mean 8–10 cm) solitary, circumscribed, cystic/cystic and solid lesions [40]. Prognosis is excellent after resection but they may rarely invade adjacent organs or metastasize to lymph nodes or distant sites.

Smears are hypercellular with complex papillae containing delicate branching fibrovascular cores covered by dense myxoid stroma (magenta-colored on Diff Quik and blue-green on Papanicolaou stain) (Fig. 85.6) [41]. Tumor cells are bland and discohesive with scant cytoplasm, coffee-bean nuclei, longitudinal nuclear grooves, open chromatin, and small peripheral nucleoli (Fig. 85.6).

SPN display *CTNNB1* or ß-catenin mutation in 95–100% which leads to nuclear and cytoplasmic ß-catenin positivity (Fig. 85.6). *CTNNB1* is part of the Wnt signaling pathway, which also includes transcription factor for immunoglobulin heavy-chain enhancer-3 (*TFE3*) and lymphoid enhancing binding factor-1 (LEF1)

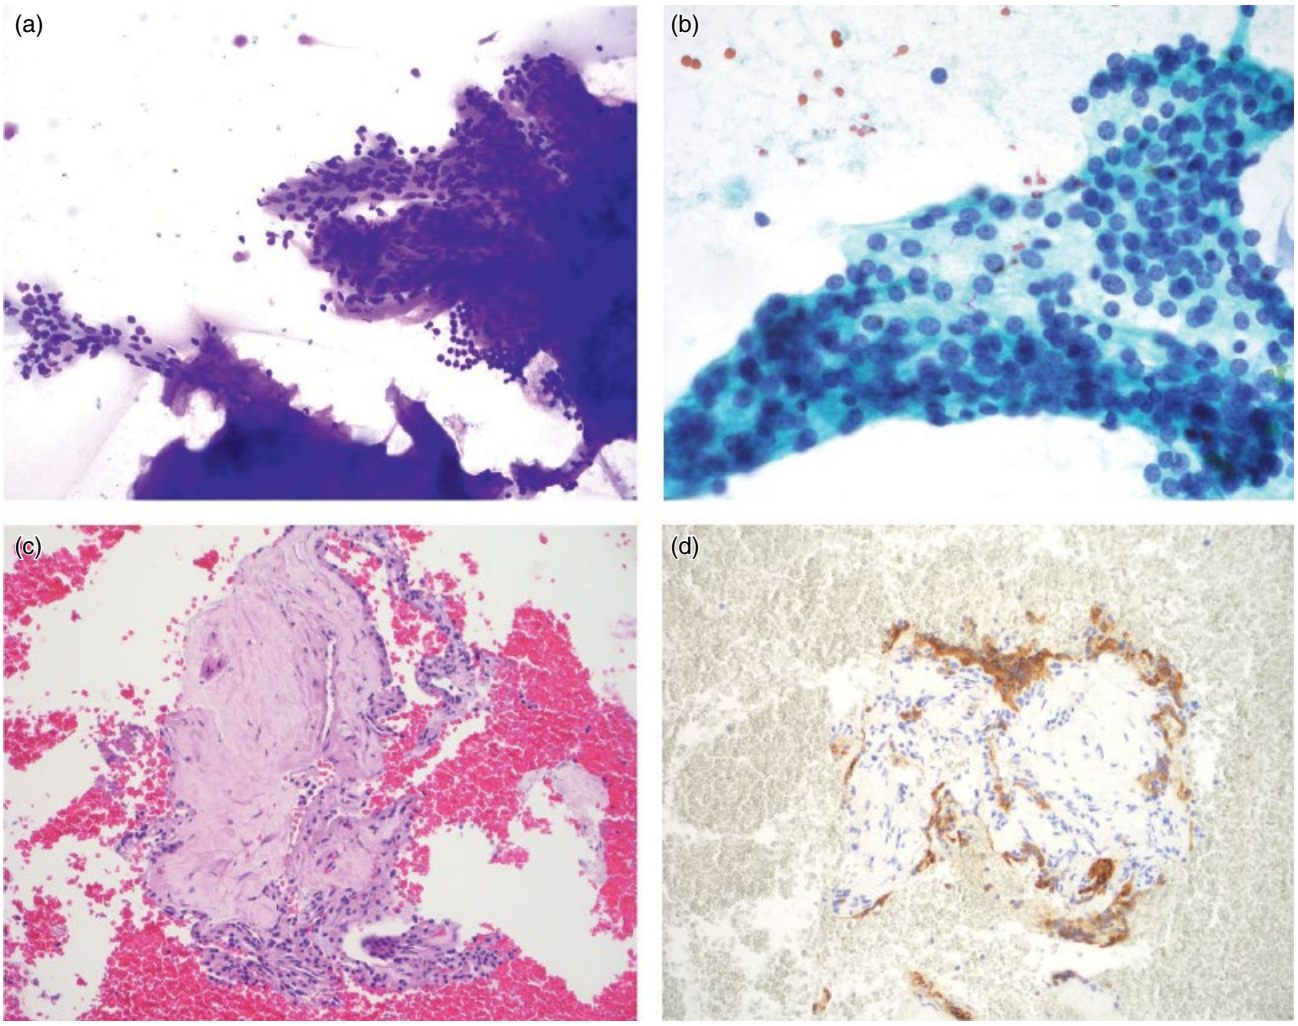

Figure 85.5 Serous cystadenoma (SCA). (a) Syncytial bland tumor cells hug adjacent fibrotic stroma (Diff Quik, 200×). (b) Bland cells in sheets have round to oval nuclei (Papanicolaou stain, 400×). (c) Cell block shows fibrotic stroma covered by a single layer of clear cells with low nuclear-to-cytoplasmic ratio (H&E, 200×). (d) Tumor cells are inhibin-positive.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 85.6 Solid-pesudopapillary neoplasm (SPN). (a) Hypercellular smear with delicate branching fibrovascular cores covered by magenta-colored myxoid stroma and lined by bland epithelioid cells, some with plasmacytoid features. (b) Fibrovascular cores covered with pale blue myxoid stroma and lined by bland epithelioid cells with high nuclear-to-cytoplasmic ratio, pale chromatin and grooved nuclei with small peripheral nucleoli (Papanicolaou stain, 200×). (c) Cell block with branching papillae (H&E, 200×). (d) Tumor cells show aberrant nuclear and cytoplasmic positivity for ß-catenin immunostain.

and results in nuclear positivity for TFE3 and LEF1 immunostains [42]. E-cadherin loss may also be seen. SPN is usually negative or only focally positive for pancytokeratin. Other positive markers include androgen and progesterone receptor, cyclin D1, CD99, and synaptophysin (but chromogranin is usually negative) [42].

SPN differential includes PanNET, IPMN, and IOPN. PanNET is characterized by clusters and single plasmacytoid cells with coarse salt-and-pepper chromatin, while SPN has pale chromatin and is negative for pancytokeratin and chromogranin. SPN papillae may resemble those in IPMN and IOPN, but SPN lacks the cytoplasmic and thick background mucin of IPMN, and oncocytic cytoplasm of IOPN. SPN cyst fluid consistently shows *CTNNB1* mutation, unlike IPMN and IOPN. *VHL*, *GNAS*, *RNF43*, and *PRKAC* alterations are not usually seen in SPN [17].

Cystic Degeneration of Solid Tumors

All solid pancreatic tumors may undergo cystic degeneration. Up to 8% of pancreatic ductal adenocarcinomas (PDAC) may show cystic change, especially large duct type, colloid and undifferentiated carcinoma, and those with squamous differentiation. Acinar cell carcinoma and neuroendocrine neoplasms may also undergo cystic change. Cystic PDAC yields malignant cells with three- to fourfold anisonucleosis, and cytoplasmic vacuoles. Well-differentiated PDAC may show drunken honeycomb sheets with overlapping nuclei and minimal pleomorphism (Fig. 85.7). Colloid carcinoma yields thick mucin and epithelial cells with high-grade cytology (Fig. 85.7). Cystic PanNET yields plasmacytoid cells, with eccentric oval nuclei and salt-and-pepper

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 85.7 (a) Well-differentiated ductal adenocarcinoma with drunken honeycomb sheets of crowded foamy cells with well-defined cell walls and relatively low nuclear-to-cytoplasmic ratio (Papanicolaou, 400×). (b) Colloid carcinoma with 3-dimensional cluster and single pleomorphic high nuclear-to-cytoplasmic ratio cells in abundant thick mucin (Papanicolaou, 400×). (c) Well-differentiated neuroendocrine tumor with clustered and single plasmacytoid cells, vague rosettes, eccentric nuclei, and coarse chromatin (Papanicolaou stain, 400×). (d) Acinar cell carcinoma with crowded tumor cells, acinar arrangement, high nuclear-to-cytoplasmic ratio and macronucleoli (Papanicoloau stain, 400×).

chromatin (Fig. 85.7). Cystic acinar cell carcinoma yields large tumor cells with hypo- or hyperchromatic nuclei, prominent cherry-red nucleoli, and abundant zymogen-rich granular cytoplasm (Fig. 85.7).

NONNEOPLASTIC CYSTS OF THE PANCREAS

1-Lymphoepithelial Cyst of Pancreas (LECP)

LECP is the most common squamous-lined pancreatic cyst. Most arise in men and present radiologically as peripancreatic cysts. LECP cyst fluid is usually yellow-white and cheesy. Cysts may have high CEA and amylase levels which should not be mistaken for mucinous cysts [43]. Cytologic preparations contain keratinaceous debris, anucleated bland squamous cells and cholesterol crystals (Fig. 85.8). Lymphocytes are usually scant because the cyst wall (where they are most abundant) is often not sampled.

2-Squamoid Cyst of the Pancreatic Duct (SCOPD)

SCOPD represent nonneoplastic cystically dilated pancreatic ducts with squamoid metaplasia [44,45]. They are radiologically small cysts (<3 cm) but may be confused with mucinous cysts. Cysts are typically lined by multilayered transitional epithelium, with a basal layer of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 85.8 (a) Lymphoepithelial cyst with anucleated squamous cells and cholesteral crystal in debris (H&E, 400×). (b–c) Pseudocyst cell block with granular debris, pigment, and rare stromal fragments (H&E, 100×). (d) Groove pancreatitis with bland spindle cells and background inflammatory cells (Papanicolaou stain, 100×).

polygonal nonkeratinizing p40/p63-positive squamoid cells, and a luminal columnar cell layer. The cytologic features of SCOPD include polygonal squamoid cells with dense eosinophilic cytoplasm with bland columnar cells with or without cytoplasmic mucin [9,44]. Cyst fluid CEA and amylase may be high raising the differential of IPMN or MCN but thick ropey mucin is not a common feature [9,44].

3-Pancreatic Pseudocyst

Pancreatic pseudocysts are the most common nonneoplastic pancreatic cysts. They lack a true epithelial-lining and commonly develop as a postinflammatory complication of pancreatitis. Aspirated fluid is dark, brown to green and turbid. Chemical analysis of cyst fluid often reveals extremely high amylase but low CEA [3,11]. Cytologic preparations are paucicellular with predominantly blood, pigmented macrophages, debris, and pigment (Fig. 85.8).

4-Paraduodenal Wall Cyst (Paraduodenal or Groove Pancreatitis)

Paraduodenal wall cysts occur in the paraduodenal groove/pancreatic head region as a result of chronic inflammation (groove pancreatitis). This causes formation of paraduodenal wall cysts on the pancreas-facing duodenal wall surface, and they are often detected in men (fifth or sixth decade) with history of smoking or alcoholic abuse [46]. Smears consist of bland spindle cells (proliferating myofibroblasts), acute and chronic inflammatory cells, multinucleated giant cells, and amorphous proteinaceous debris from

Natural History of Cystic Neoplasms: IPMN, MCN, SCN, and SPN

Rosa Klotz[1], *Thilo Hackert*[2], *and Markus W. Büchler*[1]

[1] *Department of General, Visceral and Transplantation Surgery, Heidelberg University Hospital, Heidelberg, Germany*
[2] *Department of General, Visceral and Thoracic Surgery, University Hospital Hamburg-Eppendorf, Hamburg, Germany*

Introduction

In recent years, cystic lesions of the pancreas have been identified with a rising incidence, due to the extended use of modern abdominal cross-sectional imaging modalities and due to an increasing awareness [1,2]. All types of cystic lesion or pancreatic branch-duct alteration are found in up to 25% of the elderly general population, increasing up to a 50–70% prevalence in people aged >70 years [3,4].

For adequate diagnosis and management of cystic pancreatic lesions, it is crucial to correctly differentiate between pancreatic pseudocysts and pancreatic cystic neoplasms (PCNs). In the past, inflammatory pseudocysts were thought to account for the majority of all cystic pancreatic lesions. With increasing awareness, it has become clear that PCNs are far more common than pancreatic pseudocysts, particularly in patients without a previous history of pancreatitis. While pseudocysts are benign residual lesions that occur after acute or recurrent chronic pancreatitis, PCNs display a certain potential for malignant transformation.

The most common cystic neoplasms of the pancreas are intraductal papillary mucinous neoplasms (IPMNs), mucinous cystic neoplasms (MCNs), serous cystic neoplasms (SCNs), and solid-pseudopapillary neoplasms (SPNs). As these different entities are associated with a distinct potential for malignant transformation, ranging from almost no to high risk, and their radiologic differentiation is not always precisely possible, it is challenging for clinicians to balance their decisions between the risk of surgical overtreatment and the error of keeping a malignant lesion under surveillance. Accordingly, it is important to know the natural history of PCNs.

Intraductal Papillary Mucinous Neoplasms

Intraductal papillary mucinous neoplasms are the most common cystic pancreatic lesions, making up approximately 35% of PCNs. IPMNs are characterized by mucin production as well as intraductal and papillary growth of the duct epithelium. Due to their association with the pancreatic duct system, they are classified into main-duct, branch-duct, or mixed-type IPMN, involving both the main duct and its major side branches [1,5]. It remains controversial whether mixed-type IPMN arises from the main pancreatic duct or from side branches and whether it represents a distinct subtype of IPMN [6]. Besides pancreatic intraepithelial neoplasms, IPMNs are the best described precursors of pancreatic ductal adenocarcinoma (PDAC) arising from the cyst itself. Furthermore, they also increase the risk of a syn- or metachronous additional PDAC elsewhere in the gland [7].

Main-duct and mixed-type IPMNs are characterized by dilation of the main pancreatic duct of >5 mm, segmentally or diffusely, without any other cause of obstruction [8]. The neoplastic epithelial cells produce abundant mucin with a high viscosity which cannot be drained sufficiently and leads to obstruction and secondary dilation of the affected parts of the duct system [9]. In contrast, branch-duct IPMNs occur as cysts >10 mm communicating with the main pancreatic duct without its dilation (Fig. 86.1) [2]. Although most IPMNs are basically noninvasive, they progress over time following an "adenoma–carcinoma" sequence via four grades (low-grade, borderline, high-grade dysplasia, and invasive cancer).

Recently, molecular profiling in a series of patients with coexistent high-grade dysplasia IPMN and invasive

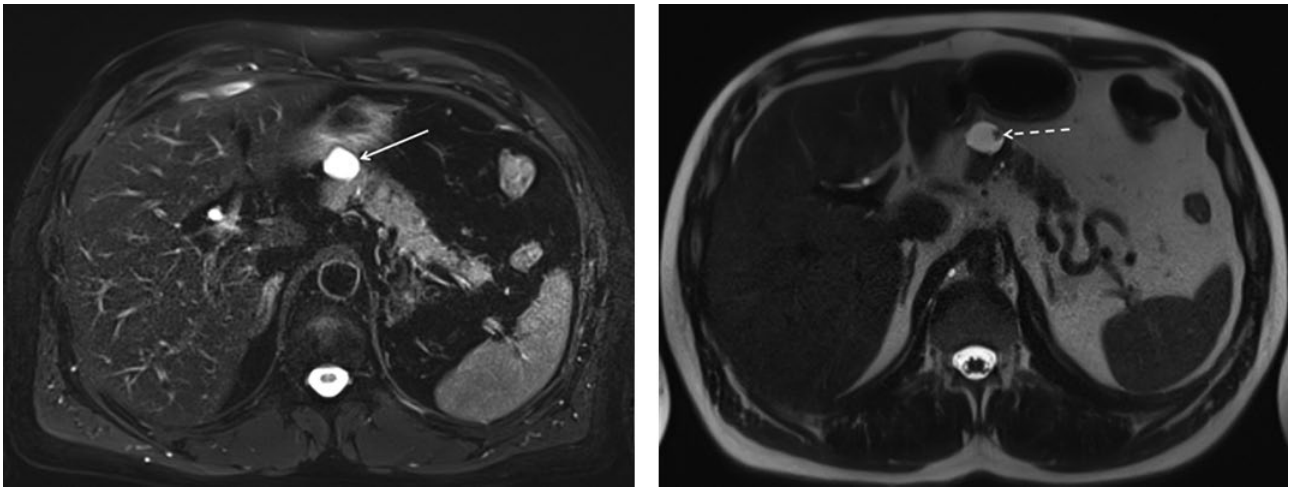

Figure 86.1 Natural history of branch-duct IPMN. A 54-year-old male patient with initial MRI finding of a branch-duct IPMN, serum CA 19-9 negative, no worrisome or high-risk features, diameter 22 mm (white arrow, left side). MRI control eight months later with development of a mural nodule (broken white arrow, right side). Indication for laparoscopic distal pancreatectomy, histopathology: branch-duct IPMN, oncocytic subtype, pTis, N0 (0/12), R0.

PDAC unveiled more tumorigenic pathways according to the proportion of shared sequence variation [10]. The malignant progression can originate from a single aberrant cell clone developing first IPMN and afterwards PDAC (the sequential subtype), from similar clonal origin with later divergence (the branch-off subtype), or from two separate sequence-variation profiles causing either IPMN or PDAC (the *de novo* subtype). The natural history of potential malignant transformation is still not well understood, and the clinical management of IPMN therefore represents a particular challenge.

Four major aspects determine the natural history of IPMN patients:

- morphologic type (main-duct, branch-duct or mixed-type IPMN)
- age at the time of diagnosis and time course of the disease
- histologic subtype (intestinal, pancreaticobiliary, oncocytic, gastric differentiation)
- grade of dysplasia at diagnosis (low-grade, borderline, high-grade dysplasia, invasive cancer).

Morphologic Type (Main-Duct, Branch-Duct or Mixed-Type IPMN)

Main-duct and mixed-type IPMNs have been reported as harboring invasive carcinoma in 11–81%, whereas the rate of invasive branch-duct IPMNs is only about 6–38% [2,11]. Lesions with high-grade dysplasia can also be regarded as "malignant" due to the consideration that this may reflect a "5-to-12" situation with a very short time to invasive cancer progression [12,13]. The dynamic of progression for the different morphologic IPMN types is not completely understood, as especially for main-duct and mixed-type IPMNs—which are basically resected by the time of diagnosis—no reliable data are available (Fig. 86.2). Furthermore, it has to be considered that radiologically defined findings of branch-duct IPMN may reveal themselves as mixed-type lesions in the histologic workup when they are resected [14]. This underlines the difficulty of evaluating an individual patient's risk on the basis of merely morphologic characteristics.

Age at Time of Diagnosis and Time Course of the Disease

Significant differences in the median age of patients presenting with benign IPMNs compared to malignant IPMNs have been reported in cohort studies of 140 and 136 resected main-duct and mixed-type IPMNs [15,16]. From both studies, the age-dependent progression to invasive IPMN can be estimated at 5–6 years as patients with benign IPMNs showed a median age of 61 and 63 years, compared to 67 and 68 years for patients with malignant findings [16]. This can be regarded as a surrogate parameter for an already longer subclinical course of preceding IPMN development by the time of diagnosis, which might be an indirect indicator for disease progression and malignant transformation over time [15,16]. A corresponding observation is the correlation between duct diameter and the risk of malignancy in main-duct IPMNs, underlining that a potentially longer disease course reflected by increased duct size leads to a higher proportion of malignant findings [17].

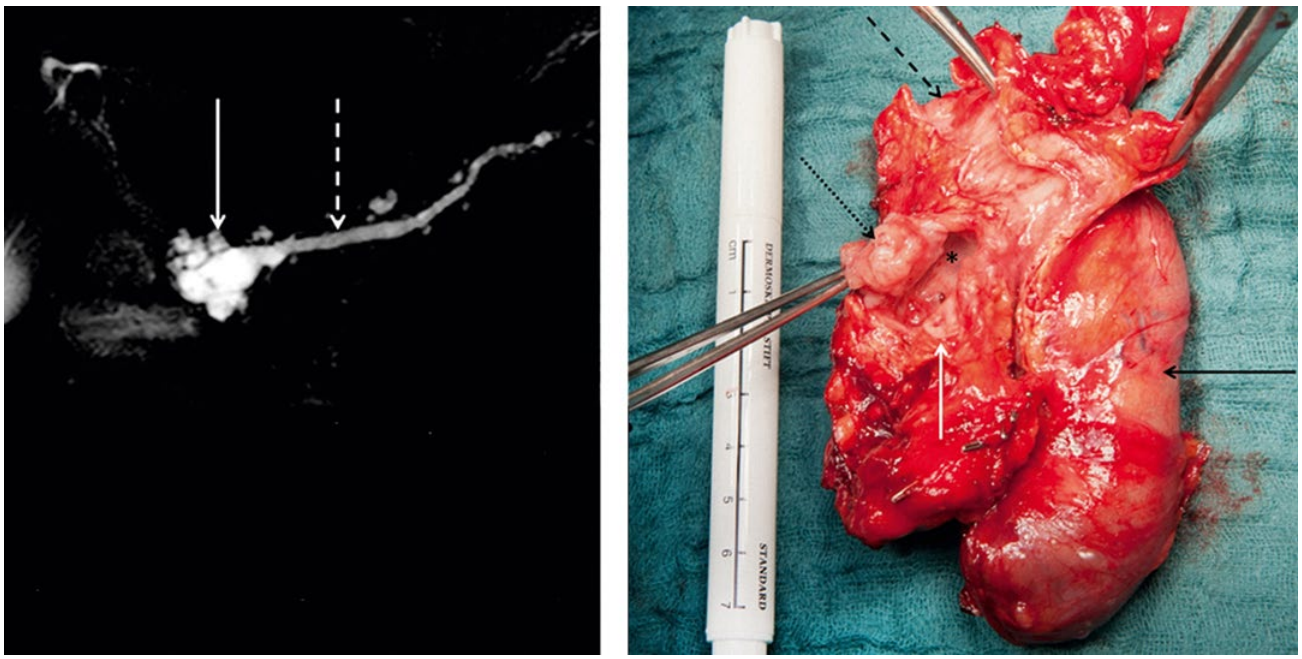

Figure 86.2 Mixed-type IPMN of the pancreatic head. MRI imaging (left side) showing branch-duct components (white arrow) and the dilation of the main duct which extends towards the pancreatic neck. Diameter of the main duct in the body of the pancreas 6 mm (broken white arrow). Partial pancreatoduodenectomy specimen of the same patient (right side). The specimen (dorsal view, black arrow: duodenum) shows macroscopic aspects of IPMN progression: dilated main duct without dysplasia at the resection margin (broken black arrow), papillary epithelium with borderline dysplasia (dotted black arrow), invasive cancer (white arrow). Histopathology: PDAC based on mixed-type IPMN, pT1, N0 (0/21), R0.

Time-dependent progression rates in patients with branch-duct IPMN, who were observed due to the lack of worrisome features, have been reported in larger studies by Sahora et al. [18] and Maguchi et al. [19]. In these studies, which included 411 and 349 patients, signs of progression occurred in 18% of the patients during median follow-up times of 26 months and 44 months, respectively. Malignant histologic features after resection were finally found in 9% and 15% of the patients. Furthermore, both studies demonstrated the development of "remote" lesions, both IPMN as well as PDAC, distant from the index lesion during observation. This underlines the hypothesis that IPMN-bearing pancreata may harbor a "field defect" of the entire gland [20].

Another aspect in this context is the synchronous occurrence of multiple branch-duct IPMNs [21]. As patients with these multifocal lesions are generally older than those with solitary IPMN findings, the "field defect" theory seems reasonable and the progression from solitary to multifocal IPMNs can be regarded as the natural course of this disease [21].

Although multiple lesions are likely to increase the long-term risk of malignant transformation, it remains controversial whether this risk has clinical relevance compared to unifocal lesions [21]. The additional risk of IPMN patients developing concomitant PDAC ranges between 3% and 9% during a 10-year period [22,23]. Whether the IPMN might play a promoting role in the development of PDAC remains unclear and the prognosis in these patients is certainly always determined by the PDAC component.

Histologic Subtypes

The differentiation of histologic subtypes (intestinal, pancreaticobiliary, oncocytic, gastric) [24] has a relevant prognostic impact. The intestinal subtype reveals a phenotype that resembles villous polyps of the colon with neoplastic epithelial cells expressing MUC2, MUC5AC, and CDX2. A recent study focused on 173 main-duct IPMN demonstrated that most main-duct IPMNs were of intestinal type with invasive components in 50% and overall invasiveness of 39% [22]. Invasive carcinomas that arise in association with an intestinal-type IPMN are usually colloidal carcinomas and show a better median survival compared to patients with PDAC (107 versus 20 months) [9,25]. The pancreatobiliary subtype is composed of branched papillary epithelia with high-grade atypia. In immunohistochemistry, it is positive for MUC1 and MUC5AC and has an associated invasive component in 90% of all cases. The associated invasive tubular adenocarcinomas are very similar to PDAC in

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

morphology and prognosis [9,26,27]. The oncocytic subtype is characterized by eosinophil cytoplasm, goblet cells and complex branched papillary epithelia expressing MUC1 and MUC6. This subtype is rare as well as a malignant transformation into an oncocytic carcinoma which shows a prognosis similar to patients with a colloid carcinoma [25–27].

Branch-duct IPMNs usually are of the gastric subtype. The typical morphology is multiple small cysts with foveolar gland epithelium, similar to the glands of the gastric antrum. A tubular adenocarcinoma can eventually arise from these IPMNs and is associated with a rather poor prognosis with a mean survival of only 45 months [9,28].

Grade of Dysplasia (Low-Grade, Borderline, High-Grade Dysplasia, Invasive Cancer)

Data on outcome with referral to the grade of dysplasia are available from various larger cohorts of surgical patients [5,22,29]. As these results always reflect the grade of dysplasia at the time of resection, a valid estimation of the time intervals between the distinct grades remains difficult. Patients post resection of IPMNs harboring noninvasive IPMN with a range of low-grade to high-grade atypia show an excellent overall and disease-specific survival prognosis of 95–100% in a follow-up of 10 years in both main-duct and branch-duct IPMN [5,22]. In invasive IPMN, poor prognosis is closely related to disease stage, potentially positive resection margins, and a potentially positive N status [22,29]. While early stages including pT1 and pN0 show a much more favorable prognosis compared to sporadic PDAC, this advantage vanishes in more advanced stages (pT2–pT4) and also positive lymph nodes in any stage result in a prognosis which is similar to PDAC [29].

In addition to the above-mentioned aspects determining the natural history and malignant potential of IPMNs, more advanced approaches enable better discrimination, although such approaches have not yet been introduced in clinical practice. Among others, a recent serum protein signature discriminating low- and high-risk IPMN patients was identified in a cohort study using an antibody microarray platform to analyze the serum proteome via a noninvasive simple blood test. Combinations of established clinical features and the newly identified serum biomarkers correctly distinguished low- and high-risk IPMNs in 93% on 1000-fold crossvalidation which enables risk stratification of IPMN patients [30]. However, larger validation studies are needed to enable more rational decision making in clinical management of IPMN patients.

As all types of IPMN must be considered as a chronic and life-long disease (unless a total pancreatectomy has been performed), the natural course of these entities requires surveillance and follow-up. Surveillance and management strategies have been determined in the International Association of Pancreatology consensus guidelines published in 2006 and updated in 2012 and 2017 [2,8,11], as well as the 2013 European evidence-based guidelines [31] and the 2015 American Gastroenterological Association guidelines [32]. These guidelines are partly conflicting not only with regard to surgical and nonsurgical management but also regarding surveillance and follow-up diagnostics and intervals after resection of IPMNs which precludes accurate clinical decision making.

A recent cohort study including patients with pathologically proven IPMN who received a pancreatic resection and were evaluated preoperatively obtained images and medical history regarding signs of progression and/or malignant features [33]. In this study, the timeliness of resection was stratified into too early (adenoma and low-grade dysplasia), timely (intermediate-grade dysplasia and *in situ* carcinoma), and too late (invasive cancer). Of 1439 patients, 438 (30.4%) were assigned to the too early group, 504 (35.1%) to the timely group, and 497 (34.5%) to the too late group. Accordingly, one-third of IPMNs reached the cancer stage before resection. Radiologic criteria for malignant conditions were detected in 53 of 382 patients (13.9%), 149 of 432 patients (34.5%), and 341 of 385 patients (88.6%) in the too early, timely, and too late groups, respectively. Of the 497 patients in the too late group, 124 (24.9%) had a previous history of watch-and-wait care [33]. These data show that a watch-and-wait policy should be applied with caution, until the biology and progression patterns of IPMN are clarified. Furthermore, follow-up data show that in a cohort of 381 resected invasive and noninvasive IPMN, 17% had recurrence of the IPMN after a median of 17 months [23]. Within this study, 33 patients had only partial resection of multifocal disease with branch-duct IPMN left in the pancreatic remnant. The residual branch-duct IPMNs with a median size of 10 mm at the date of resection grew within a median follow-up of five years to a median size of 13 mm.

In a cohort of 130 patients who had undergone partial pancreatic resections for noninvasive IPMNs, He et al. showed that 17% developed lesions suspicious for new or progressive IPMN within a median time of 46 months [34]. Within this disease progression cohort, some patients developed high-grade dysplasia and invasive cancer. Another 12% of the cohort showed neither new IPMN nor progression in known residual IPMNs.

Within the literature, the recurrence rates vary between 8% and 57% [15,23,34,35]. However, even patients with noninvasive IPMN might have an estimated

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

average recurrence rate of 25% of remote IPMN and 7% for developing pancreatic cancer within five years after resection, which underlines the importance of structured and long-term follow-up.

Mucinous Cystic Neoplasms

Mucinous cystic neoplasms generally occur in perimenopausal women with a median age of 48 years. MCNs are often located in the distal body or tail of the pancreas (>90%) with a mean size of 6.5 cm in diameter at diagnosis. Macroscopically, MCNs show a uni- or multicystic pattern with a thick wall and potentially solid components without any communication to the pancreatic duct system. An ovarian-like stroma is typical and pathognomonic for the histology of MCNs [36].

Similar to IPMNs, most MCNs are noninvasive, but show a risk of an "adenoma–carcinoma" sequence over time. In 15–20% of all cases, MCNs harbor, at least focally, an invasive component [37]. As data show that patients with an invasive MCN are significantly older (median 3–10 years) than those with a noninvasive MCN, a time-dependent tumor progression is suggested, comparable to that in IPMN [2]. It has been suggested that ectopic ovarian stroma in the pancreatic tail might release hormones and growth factors that stimulate endodermally derived epithelium to progress and form PCNs. This hypothesis is supported by the fact that rapid growth of pancreatic MCNs was seen in women during pregnancy. It has been reported that mural nodules on imaging, lesion size >6 cm and calcification of the cyst wall are associated with the presence of a tubular-type invasive carcinoma very similar to PDAC [38–41].

Since nearly all reported MCNs have been resected, the natural history of MCN is still unknown and recommendations are based on findings from resection specimens revealing the above-mentioned malignancy rates. When an MCN is diagnosed, a distal pancreatectomy is indicated in most cases due to the young age of the patients and the inability to differentiate securely between a benign and malignant lesion. For most patients with noninvasive MCNs, complete resection is curative as these lesions are solitary and show no recurrence [2]. Postoperative surveillance is not mandatory and would require life-long high-resolution imaging associated with high costs without any advantages for the patients [2,42]. In contrast, follow-up after resection of invasive MCN should be performed similar to PDAC [42]. The five-year survival of patients presenting with invasive MCN has been described to be as high as 62%, being worse for elderly patients and for patients with more advanced tumor stages [43].

Serous Cystic Neoplasms

Serous cystic neoplasms are typically located in the pancreatic body and tail and show no significant potential for malignant transformation. The incidence of SCNs is slightly higher in women than in men, with a peak at the age of 60 years. In abdominal imaging, SCNs have a micro- or macrocystic appearance with a spongy structure. In some cases, they also present with a solid growth pattern. On histopathology, they typically are composed of cysts lined by a single layer of cuboid epithelial cells filled with glycogen [36,44]. A preoperative distinction of SCN from MCN is feasible in most cases due to significant differences in imaging. SCNs are usually sporadic, but some arise in patients with von Hippel–Lindau (VHL) syndrome. In patients with VHL syndrome, SCNs are commonly multiple. These patients show a loss of heterozygosity of the VHL gene [45,46]. Sporadic SCNs have a somatic mutation of the VHL gene in up to 50%, with inactivation of the VHL tumor suppressor protein [45–47], and often show a mutation in the *TBC1D3* gene, also known as *PRC17*, but no mutations in the genes typically mutated in mucin-producing neoplasms, such as *KRAS*, *RNF43*, or *TP53* [45,47].

At diagnosis, micro- and macrocystic SCNs have a mean size of 4–6 cm and approximately 50% of all patients are asymptomatic [44,48]. Depending on localization and size of the lesion, symptoms including abdominal pain, discomfort, jaundice or fatigue are reported. Malignant transformation of SCN with the occurrence of a serous cyst adenocarcinoma is very rare and has only been described in a few case reports [49]. Thus, for asymptomatic patients with a SCN of <4 cm in diameter and without criteria for malignancy on preoperative imaging, surveillance is indicated rather than surgical resection.

The natural course of SCN is characterized by a gradual increase in diameter (0.6 cm/year on average). The growth rate seems to depend on the initial tumor size as small SCN (<4 cm) show a significantly slower growth rate of 1–2 mm/year than larger lesions (>4 cm) in which annual growth rates of up to 2 cm can be observed [48]. Consequently, besides the size, growth rate during surveillance may have an influence on the decision for surgery to avoid local complications of compression. Following resection, recurrence risk is extremely low and no structured follow-up is recommended [42].

Solid-Pseudopapillary Neoplasm

The SPN, also known as a Frantz tumor, was first described in 1959. SPNs are rare cystic neoplasms that account for approximately 1–2% of all pancreatic tumors [50]. They

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

usually occur in women with a median age of 30 years and are most frequently located in the tail of the pancreas. SPNs are classified as malignant due to the potential for lymphatic spread, recurrence, and distant metastases [51]. As all reported series include mainly patients who underwent resection, the natural history of SPN without resection (i.e., growth dynamics) cannot be determined. Anecdotal reports on nonsurgical treatment have shown that both long-term survival with locally limited tumor manifestation and also aggressive systemic spread with short survival times are possible [52].

At diagnosis, SPNs have a mean size of 8 cm and are located in the body and tail of the pancreas in 60% of patients [51,53]. Their macroscopic morphology varies from pure solid to entirely cystic [54]. Tissue analysis of resection specimens has shown that characteristic mutations in exon 3 of the β-catenin gene occur in 83–100% of SPNs [55,56]. Moreover, the absence of other common mutations, such as *KRAS*, *SMAD4* or *TP53*, distinguishes SPNs from other neoplasms of the pancreas [56,57].

Following complete surgical resection, the long-term outcome of SPN is excellent although approximately 6% of patients show locally advanced tumors (vascular involvement, lymph node metastases) and 8% present with distant metastases [51]. The most comprehensive review including 2285 resected patients demonstrated that 95.6% of the patients are disease free during long-term observation. The time to recurrence in the remaining 4.4% is more than four years and final tumor-related mortality is 1.5% [51].

Despite this overall favourable prognosis, SPN must be considered as a tumor entity with a basically malignant course and complete surgical resection is indicated in all patients who qualify for surgery. Furthermore, life-long follow-up (i.e., annually) is mandatory [42].

Surveillance or Surgical Treatment in Asymptomatic Cystic Neoplasm

Klaus Sahora[1] *and Carlos Fernández-del Castillo*[2]

[1] *Department of General Surgery, Medical University Vienna, Vienna, Austria*
[2] *Department of Surgery, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA*

Introduction

Our knowledge regarding cystic lesions of the pancreas has evolved since the initial publication of this chapter half a decade ago, and now offers a safer and more individualized approach to most patients. In cystic neoplasms, such as solid pseudopapillary neoplasms, mucinous cystic neoplasms, cystic neuroendocrine tumors, and main-duct IPMN, the accepted approach is still surgical resection if the patient is a suitable candidate [1,2]. Otherwise, observation for serous cystic neoplasms (SCN) and main-branch IPMN has proved to be safe [3].

However, in a majority of patients with small lesions, identification of the cyst subtype is either not feasible or uncertain. Based on observational data, several treatment algorithms have been proposed for these unclassified cystic lesions, facilitating the decision on whether to operate or observe [4–6]. Most of these recommendations are based on patient symptoms and morphologic cyst characteristics. Symptomatic patients should strongly be considered for surgery, while in the absence of symptoms, observation is recommended in lesions without suspicious morphologic features.

Further aspects such as age, comorbidities, quality of life, and assumption of costs by the local healthcare system should also be considered when counseling a patient with an asymptomatic cystic lesion of the pancreas. A recent review of three decades from our department at the Massachusetts General Hospital showed how noticeably the diagnostic work-up and indications for surgery have changed over time [7]. With greater availability of endoscopic ultrasound (EUS) over the decades, the concordance between preoperative and final histopathologic diagnosis increased from 45% to 68%, and is currently 80%.

Over time, resections for mucinous cystic neoplasm (MCN) and SCN have decreased significantly, while the number of resected cystic neuroendocrine tumors doubled. The frequency of pancreatic resections for purely benign lesions decreased from 37% to 16%, with a low surgical mortality of 0.9%. Moreover, diagnosis of MCN became less frequent and the number of IPMN more dominant over time.

Rationals for Surveillance or Surgery in Asymptomatic Cystic Neoplasm

After an early period of radical resection of all pancreatic cystic tumors, growing evidence from larger case series caused a transition towards a more selective and observational approach. The rationales behind selective surveillance in asymptomatic patients with a pancreatic cyst are: (i) some cystic lesions, such as SCN of the pancreas, never progress into malignant tumors; (ii) in others that can become malignant, an adenoma–carcinoma transformation takes many years or may never occur; and (iii) cystic lesions with malignant potential normally exhibit suspicious features that can distinguish them from those that are benign. Overall, it can be assumed that the risk that a cystic lesion is malignant at the time of diagnosis does not exceed 0.01%, but it is greater for cysts >2 cm [8]. Further estimation based on collective data from large case series suggests that the percentage of patients developing an invasive carcinoma is approximately 0.24% per year [5].

A recent population-based study from Germany of 1077 healthy individuals who underwent MRI screening showed that 46% harbored cystic lesions of at least 2 mm [9]. The prevalence was associated with higher

age, higher body mass index (BMI), and diabetes mellitus. Thirteen percent of primary cyst-free patients developed a pancreatic cyst within a five-year follow-up, otherwise a cyst was no longer detectable in 1.6% and none of the cyst-harboring patients developed pancreatic cancer. Likewise, a dual-center retrospective analysis from Medical University Vienna and the Verona Pancreatic Center of 376 incidentally discovered and 10-year nonobserved small cysts of the pancreas demonstrated that the risk for associated pancreatic cancer was low (1.6%) [10]. In both studies, cyst size was moderately small (<15 mm). However, other authors claim the risk of malignancy in pancreatic cystic lesions, especially IPMN, should not be underestimated. In a large surgical series from Heidelberg, 9% of patients already had invasive carcinoma at the time of surgery and had been under surveillance for at least one year [11].

Ideally, patients should only be recommended for pancreatic surgery if this would prevent death from pancreatic cancer or if resection is required for relief of symptoms. In patients with a high comorbidity burden (measured by an Charlson comorbidity score of ≥7), an analysis from our institution demonstrated that the absolute majority of patients with unsuspicious cystic lesions, assumed to be branch-duct IPMN, died from causes other than IPMN carcinoma [12]. Therefore, it is reasonable to question whether further surveillance should be limited only to those patients who can benefit from major pancreatic surgery should the lesion develop concerning features.

Treatment Guidelines for Asymptomatic Cystic Neoplasms

The 2017 revised International Association of Pancreatology (IAP) guidelines for the management of IPMN and MCN of the pancreas [4,6,13], the American Gastroenterological Association (AGA) guidelines on management of asymptomatic neoplastic pancreatic cysts [5] and the 2018 European evidence-based guidelines on pancreatic cystic neoplasms (ESG) [14] have been adopted by most physicians. At the Massachusetts General Hospital and the Medical University Vienna, surveillance of asymptomatic cystic neoplasm of the pancreas is conducted according to IAP guidelines (Fig. 87.1). There are several differences between these proposed algorithms (Table 87.1).

Primarily, the AGA guidelines have been designed for asymptomatic cysts in general, while the IAP and ESG algorithm focuses on the management of branch-duct IPMN. All the guidelines established a list of concerning or worrisome features on which further diagnostic workup, surveillance or surgery is recommended. The IAP and ESG guidelines agree on most points regarding relative and absolute surgical indications, while the AGA only suggests upfront surgery if a solid mass with associated main duct dilation is present. The IAP recommends further evaluation by EUS ± fine needle aspiration (FNA) if any worrisome feature is present. If a definitive mural nodule/solid component and/or main duct involvement is confirmed by EUS, surgery should be considered in all fit patients according to the IAP guidelines. These guidelines also recommend surgery if the EUS shows concerning features or the cytology shows high-grade dysplasia or more. The AGA guidelines, by contrast, only recommend surgery if two concerning features are present and the cytologic analysis of the fluid or cyst wall (obtained by EUS) is either malignant or suspicious for high-grade dysplasia. The ESG guidelines only recommend EUS if the results are expected to change clinical management and only if the diagnosis is not established by cross-sectional imaging.

While this direct relation between cyst size and the risk of malignancy has been investigated and described in numerous studies, the relative meaning of cyst size change over time has been given less attention. In 2017 and 2018, the revised IAP and European evidence-based guidelines on pancreatic cystic neoplasms introduced a rapid growth rate >5 mm/two years as a worrisome feature (relative surgical indication) and favored resection in young patients or observation at very short intervals by EUS and/or magnetic resonance imaging (MRI) (3–6 months) [13–15].

For further surveillance, the AGA proposed an annual interval once after diagnosis, followed by a two-year interval and end of surveillance after five years. By contrast, the IAP surveillance frequency is based on cyst size: <1 cm, 2–3 years; 1–2 cm, yearly for two years, then longer if no change; 2–3 cm, EUS in 3–6 months, then longer interval alternating MRI with EUS as appropriate; ≥3 cm, close follow-up with EUS every 3–6 months. ESG guidelines recommend an initial follow-up after six months, followed by yearly clinical evaluation with Ca 19-9 and MRI/EUS in patients without an absolute or relative surgical indication. As proposed by the AGA guidelines, discontinuation of follow-up in stable unsuspicious cysts after five years may be a cost-effective approach but is not recommended in surgically fit patients. A retrospective analysis of our cyst database revealed that the risk for malignancy is still 5.5% beyond five years of surveillance and size-stable cysts can still progress into invasive cancer [14]. Of note, cystic lesions that were 1.5 cm or less and remained so for more than five years had a very low risk of malignancy that was no different from that of the general population.

Surveillance in "Surgically Unfit" Patients

There is only limited information regarding the natural course in frail patients, who are not good surgical candidates, undergoing surveillance with worrisome features or high-risk stigmata. In a multicenter analysis of 281 conservatively managed patients harboring worrisome features or high-risk stigmata (median follow-up 51 months), IPMN-Ca mortality was only 4% in branch-duct IPMN with worrisome features versus 43% in those with main-duct IPMN and high-risk stigmata [16]. Overall, 57 patients (20%) died, but only 12% had progression towards IPMN carcinoma and IPMN-related mortality was only 9%. A recent study showed that cystic lesions with a single stable worrisome feature have a relative low risk of malignancy, while those developing an additional worrisome feature or high-risk stigmata under observation are likely to harbor high-grade dysplasia [17].

Quality of Life: Surgery versus Surveillance

The major objective in treating a patient with an asymptomatic and unsuspicious cystic neoplasm is to prevent or detect the development of pancreatic malignancy. There is controversy over whether or not this should include high-grade dysplasia (what we previously referred to as carcinoma *in situ*) or only invasive cancer. Given the poor prognosis of invasive cancer, most clinicians in the field feel that the goal of surveillance should be the detection of high-grade dysplasia. Repeating imaging studies, invasive diagnostic procedures and major pancreatic surgery are indispensable requirements to maintain this aim.

However, the majority of case series and actual guidelines often neglect issues relating to quality of life, patient preference or postsurgical functional status. In a unique analysis, Weinberg et al. used decision analysis with Markov modeling to compare competing management strategies in a patient with pancreatic head cysts [18]. In their study, they found that surgery remains the superior strategy for maximizing quality of life in patients who are between 65 and 75 years of age with cysts ≥3 cm, but concluded that patients >85 years have improved quality of life when managed with surveillance. They assume that poor quality of life experienced postoperatively often outweighs the minimal benefit derived from surgery in this population. Analogous consideration has been reported regarding prostate cancer in the elderly, where "watchful waiting" is often more appropriate than radical prostatectomy [19]. Van der Gaag et al. reported that after cyst resection, long-term quality of life is equal to healthy references and concluded that the excellent long-term overall outcome justifies proceeding with surgery once an indication for resection has been made [20]. Equally, evaluation of Italian patients with branch-duct IPMN under observation revealed that their quality of life did not deviate from the normal population. Further psychologic questionnaires conducted at basal evaluation and during follow-up demonstrated that the majority of patients showed no signs of anxiety or depression [21].

Cost-Effectiveness of Each Approach

In the light of continuously increasing healthcare costs and a restrictive compensation policy by insurance companies, optimal cost-effective management of asymptomatic pancreatic cystic neoplasm is increasingly relevant. Repeated costly MRI imaging studies for patients under surveillance must be weighed against a more aggressive surgical approach and follow-up with any intervention or stop of surveillance in selected patients. Yet, only a view studies have focused on cost-effectiveness in the management of pancreatic cystic neoplasm.

Das et al. used a Markov model with a third party payer perspective, comparing follow-up without any specific intervention with an aggressive surgical approach and initial EUS with FNA with cyst fluid analysis for risk stratification and resection of all mucinous cysts [22]. The strategy based on risk stratification of malignant potential by EUS with FNA and cyst fluid analysis was the most cost-effective and yielded the highest quality-adjusted life-years. Researchers from our own institution reviewed the cost-effectiveness of the IAP consensus guideline implementation in the management of branch-duct IPMN [23]. Three scenarios based on 60-year-old patients with branch-duct IPMN were analyzed: surveillance using consensus guidelines for surgical resection (surveillance strategy), surgical resection based on symptoms without surveillance (no surveillance strategy), and immediate surgery (surgery strategy).

Surveillance according to the IAP guidelines is a cost-effective strategy in the management of branch-duct IPMN in the head of pancreas when compared to no surveillance or immediate surgery. However, given the large number of patients who are found to have incidental pancreatic cysts, and the lack of endpoint in surveillance, there is a clear need for additional triage strategies to identify groups of patients with higher risk and those with negligible risk, where potentially surveillance could be stopped early on. These potential strategies include

analysis of cyst fluid for unique markers and identification of circulating tumor cells, exosomes, or free DNA. For example, mAb Das-1, a monoclonal antibody against a colonic epithelial phenotype investigated at our institution, showed high reactivity, both in EUS-FNA cyst fluid samples (sensitivity 89%, specificity 100%) and histologic specimens from resected high-grade IPMN (sensitivity 85%, specificity 95%) [24,2]. Recently, a cost-effective preoperative nomogram for predicting grade of dysplasia in IPMN with a strong objective predictive power (c-index 0.82) was proposed [26]. Combination of this nomogram with cyst fluid protein analysis resulted in increased discrimination of low- versus high-grade lesions (c-index 0.84) [27].

Artificial Intelligence in the Detection and Surveillance of Cystic Neoplasms

Linda C. Chu and Elliot K. Fishman

The Russell H. Morgan Department of Radiology and Radiological Science, Johns Hopkins University School of Medicine, Johns Hopkins Hospital, Baltimore, MD, USA

Introduction

Pancreatic cysts are often incidentally detected on cross-sectional imaging, from approximately 2% of abdominal computed tomography (CT) to 20% of magnetic resonance imaging (MRI) exams [1]. These pancreatic cysts represent a spectrum of pathologies ranging from benign (e.g., serous cystadenoma [SCA], pseudocyst), cysts with malignant potential (e.g., mucinous cystic neoplasm [MCN], intraductal papillary mucinous neoplasm [IPMN]), to cystic or necrotic appearance of overt malignancies (e.g., pancreatic ductal adenocarcinoma [PDAC], pancreatic neuroendocrine tumor [PNET]). These pancreatic cysts can have overlapping clinical and imaging features and can be difficult to diagnose accurately [1]. Cysts with high-risk features such as mural nodules, wall thickening, and main pancreatic duct dilation are often referred for endoscopic ultrasound (EUS) and fine needle aspiration (FNA) and/or surgical resection [1,2]. Current management guidelines recommend serial monitoring of cysts with low-risk characteristics for five years [3] or even 10 years [1], which can be a significant economic burden to the healthcare system [4] and source of patient distress.

There is much optimism that artificial intelligence (AI) may be able to extract digital clinical and imaging data that can lead to earlier disease diagnosis, more accurate disease classification, and the identification of prognostic markers to optimize patient management. This chapter will provide a brief overview of AI, review current AI applications in pancreatic cysts, and discuss future directions for the role of AI in the management of pancreatic cysts.

Brief Overview of Artificial Intelligence

Artificial intelligence can be broadly defined as the computer systems that perform tasks that ordinarily require human intelligence [5,6] (Fig. 88.1). AI can help automate the relatively mundane tasks in medicine (e.g., data entry, lesion measurement) and allow physicians to focus on higher level cognitive tasks that fully utilize their expertise. AI can also decipher patterns in large volumes of multidimensional data, which may not be fully appreciated by humans, and this additional insight may potentially improve human performance.

Machine learning is a subset of AI that trains the algorithms to perform tasks by learning patterns from the data, instead of by explicit programming [6]. The machine learning algorithms can be trained using supervised or unsupervised learning methods. In supervised learning, the algorithm is provided with annotated "ground truth" labels, which is used as feedback to improve the algorithm in an iterative process. The ground truth is the reference standard, which can range from normal versus abnormal at the individual patient level, to detailed slice-by-slice labeling of medical images. In unsupervised learning, the algorithm determines how to classify the data into groups, without the assistance of ground truth labels [6].

Deep learning is a subset of machine learning. It uses convolutional neural networks (CNNs), which are composed of layers of interconnected nodes, inspired by the architecture of biologic neural networks. The principles for deep learning were first developed in the 1950s, but the early applications were limited by computer hardware. The convergence of powerful parallel computing hardware, abundance of medical and nonmedical

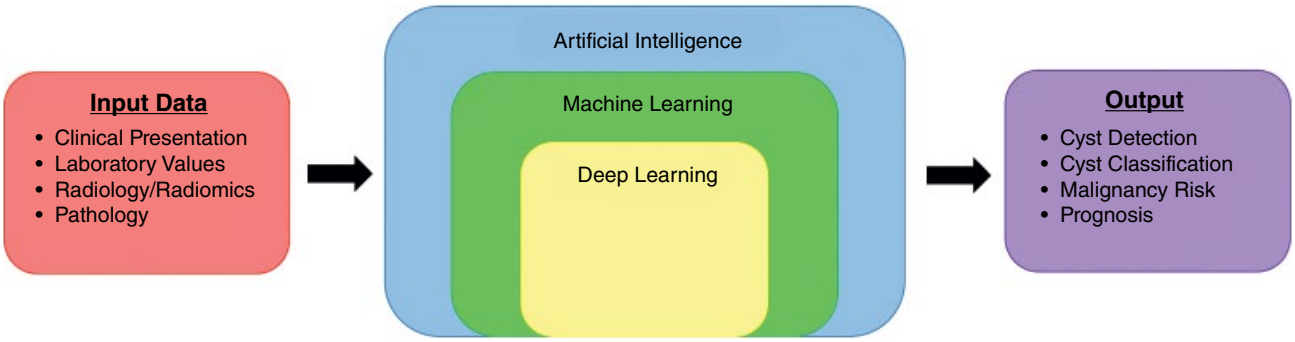

Figure 88.1 Potential role of artificial intelligence in pancreatic cystic neoplasms. Deep learning and machine learning are subsets of artificial intelligence (middle column) that can build models based on diverse sources of input data (left column), and generate output prediction on cyst detection, classification, and prognostication (right column).

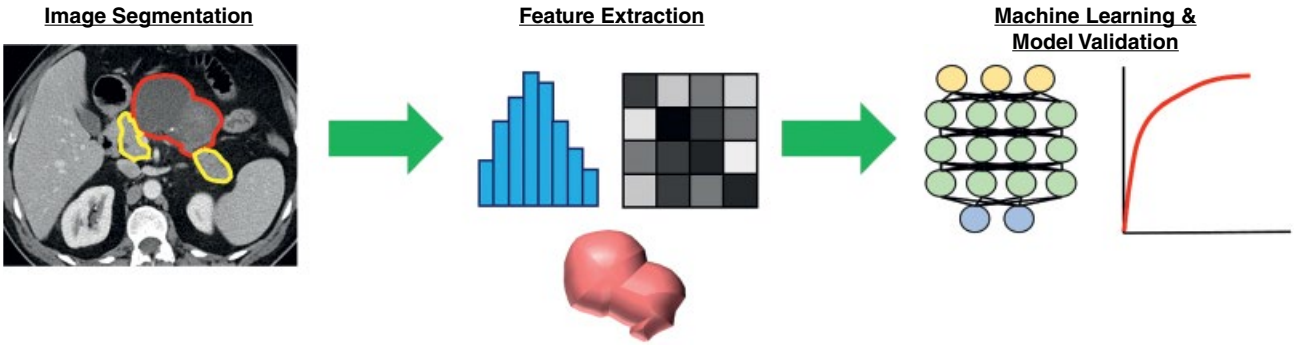

Figure 88.2 Process of radiomics. The radiologic images are first manually segmented to define the region of interest (left column). Quantitative image features, including signal intensity, texture, and shape (middle column), are extracted from these regions of interest. These quantitative features are analyzed with machine learning techniques for model development and validation (right column).

training data, and improvements in network architectures and training techniques has significantly improved the performance of these deep neural networks [5,6].

The input data for machine learning can be derived from various sources, including patient demographics, clinical presentation (e.g., presence or absence of specific symptoms), laboratory values, medical images (e.g., radiology, pathology), and disease diagnosis. Many current AI applications involving radiologic images employ a quantitative feature extraction step before analysis with machine learning. Radiomics is a feature extraction method that converts images into high-dimensional mineable quantitative features [7] (Fig. 88.2). The radiologic images are first manually segmented to define the region of interest (ROI), which is a labor-intensive process that requires expertise in imaging anatomy and pathology. Quantitative image characteristics, including signal intensity, shape, texture, and higher-order features, are then extracted from these ROIs [8]. Signal intensity features are derived from histogram distribution of individual voxel signal intensities and include measures of central tendency and the shape of the distribution. Shape features are extracted from three-dimensional surface masks of the ROI. Texture features take into account the correlation of voxel signal intensities in relation to surrounding voxels in all three dimensions. Higher-order statistics add a filtration step prior to feature extraction [9]. This process typically generates hundreds of features, and a feature reduction step is performed to eliminate redundant features and identify the most relevant ones.

Pancreatic Neoplasm Detection

Computed tomography is one of the first-line imaging modalities for suspected pancreatic pathologies, but imaging features of these pancreatic pathologies can be subtle and overlooked by the radiologist at the time of interpretation. There are a few preliminary reports demonstrating the potential role of deep learning in facilitating automatic detection of pancreatic cancer (Table 88.1), analogous to how computer-aided detection (CAD) in mammography assists radiologists in breast cancer detection (10).

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Table 88.1 Representative peer-reviewed studies of machine learning in the detection of pancreatic pathology.

Study	Study population	Imaging modality	Machine learning and validation	Clinical accuracy or AUC of best model	Machine learning accuracy or AUC of best model
Liu [11]	752 PDAC 490 controls	CT	CNN Split sample External validation	94.4	98.6 (0.997) EV: 83.2 (0.920)
Ma [12]	222 PDAC 190 controls	CT	CNN Crossvalidation	92.2	95.5

AUC, area under the curve; CNN, convolutional neural network; CT, computed tomography; EV, external validation; PDAC, pancreatic ductal adenocarcinoma.

Liu *et al*. trained a CNN from CT images obtained from 752 patients with pancreatic cancer and 490 healthy controls, and showed that the CNN model was 97.3–99.0% sensitive, 98.9–100% specific, and 98.6–98.9% accurate in the differentiation of pancreatic cancer from healthy controls [11]. The CNN model achieved superior sensitivity in pancreatic cancer detection compared to radiologists who originally interpreted the studies (97.3–99.0% vs 91.7–94.4%), and it was able to correctly identify 11/12 (92%) of the pancreatic cancers that were missed by the original radiologists' interpretation. The authors validated their model on external test set, which demonstrated 79.0% sensitivity, 97.6% specificity, and 83.2% accuracy, with the caveat that the pancreatic cancer cases and the healthy control cases came from different institutions, which could affect the performance of the model.

Ma *et al*. similarly constructed a CNN to differentiate between CT images obtained from 222 patients with pancreatic cancer and 190 healthy controls, and showed that the CNN achieved superior accuracy in a 10-fold crossvalidation (95.5%), compared to gastroenterologists (92.2%) and trainees (73.6%) [12].

These promising results obviously need to be further validated in future studies, but they support the potential role of AI to serve as a "second reader" to decrease the number of early, potentially curable cancers that are missed. This may be especially important in rural or resource-poor settings where access to pancreatic imaging expertise may not be readily available, and these AI programs may help elevate the performance of an average clinician to the level of an expert. Such deep learning-based strategies can be adapted to facilitate the automatic detection of pancreatic cysts [13], and surveillance of these pancreatic cancer precursors may lead to earlier pancreatic cancer detection.

Classification of Pancreatic Cysts

Pancreatic cysts may share overlapping clinical and imaging features and studies have shown that AI can potentially improve the classification accuracy of pancreatic cysts. Studies have employed different strategies in pancreatic cyst classification (Fig. 88.3, Tables 88.2, 88.3):

- multi-class approach differentiating each type of pancreatic cyst
- binary classification differentiating benign cysts from cysts with malignant potential
- binary classification of high-grade versus low-grade dysplasia in mucin-producing cysts.

Dmitriev et al. reported that a multi-class machine learning model based on 134 pancreatic cystic masses could differentiate SCA, IPMN, MCN, and SPN (solid pseudopapillary neoplasm) with an accuracy of 83.6% in a 10-fold crossvalidation [14]. Shen et al. developed a model from 164 pancreatic cystic masses and achieved an accuracy of 79.6% in differentiating three types of cysts, including SCA, MCN, and IPMN [15]. Other studies used a binary classification to differentiate SCA from other pancreatic cystic neoplasms, with accuracy ranging from 69.2% to 94.7% (see Table 88.2). The combination of the radiomics machine learning model and the clinical model could further increase the diagnostic accuracy to 76.9–98.2% [16–21]. The rationale for this strategy to differentiate SCA from other pancreatic cystic neoplasms is that increased confidence in the diagnosis of SCA, a benign entity, can safely reassure patients and avoid any unnecessary clinical and imaging follow-ups, biopsies or surgeries, and can reduce healthcare costs.

Another important AI application is the prediction of dysplasia grade in mucin-producing cysts. Our current IPMN management guidelines are designed to emphasize the sensitivity of malignancy detection [2], at the expense of specificity. A recent 15-year multi-institution study showed that only 25% of branch-duct IPMN and 66% of main-duct IPMN in patients who underwent surgical resection had high-grade dysplasia or invasive carcinoma [22]. Therefore, better assessment tools are needed for IPMN risk stratification and to appropriately triage patients who require surgical resection.

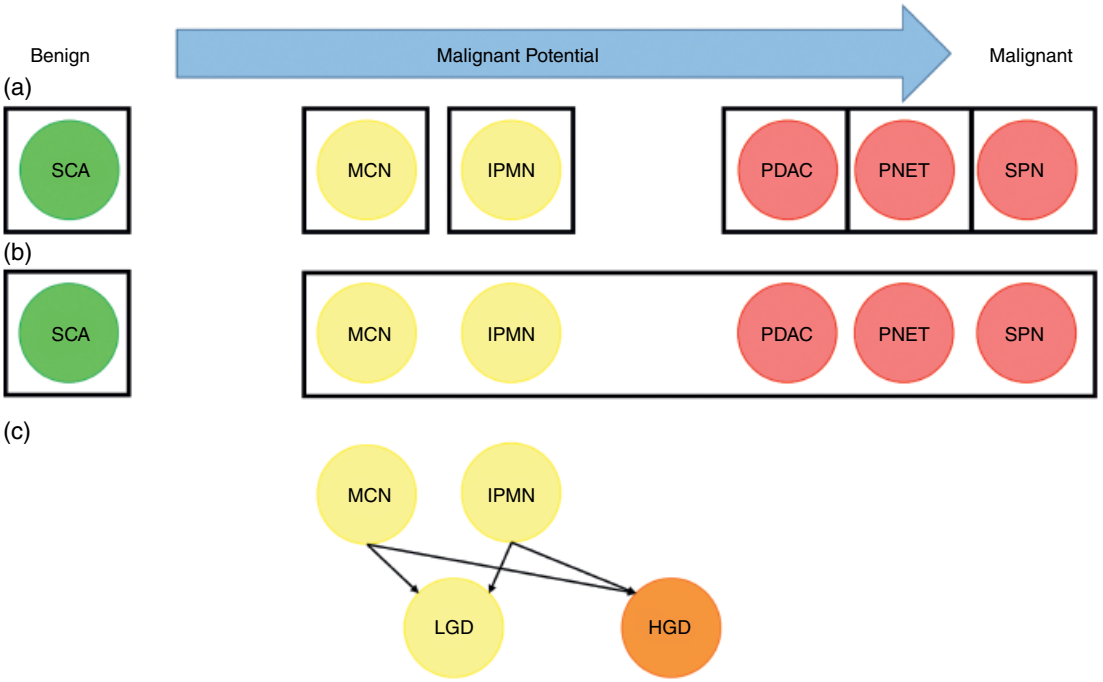

Figure 88.3 Current artificial intelligence strategies in the classification of pancreatic cysts. Row A illustrates the strategy of predicting each individual class of pancreatic cysts, where each cyst type (colored circle) is bounded by separate black boxes. Row B illustrates the strategy of differentiating pancreatic serous cystadenoma (SCA) from all other cyst types (grouped in black rectangle). Row C illustrates the risk assessment of mucin-producing into low-grade dysplasia or high-grade dysplasia. HGD, high-grade dysplasia; IPMN, intraductal papillary mucinous neoplasm; LGD, low-grade dysplasia; MCN, mucinous cystic neoplasm; PDAC, pancreatic ductal adenocarcinoma; PNET, pancreatic neuroendocrine tumor; SCA, serous cystadenoma; SPN, solid pseudopapillary neoplasm.

Table 88.2 Representative peer-reviewed studies of machine learning in the classification of pancreatic cyst type.

Study	Pancreatic cyst types	Imaging modality	Machine learning and validation	Clinical accuracy or AUC of best model	Machine learning accuracy or AUC of best model	Combined accuracy or AUC of best model
Dmitriev [14]	74 IPMN 14 MCN 29 SCA 17 SPN	CT	CNN Crossvalidation	N/A	83.6	N/A
Shen [15]	76 SCA 40 MCN 48 IPMN	CT	Radiomics + SVM, RF, and CNN Split sample	N/A	79.6	N/A
Yang [16]	53 SCA 24 MCN	CT	Radiomics + RF, LASSO Split sample	N/A	83.0 (0.75)	N/A
Wei [17]	102 SCA 74 IPMN 35 MCN 49 SPN	CT	Radiomics + SVM Split sample	0.774	0.837	0.837
Xie [18]	31 MCN 26 SCA (macrocystic)	CT	Radiomics	77.2 (0.775)	94.7 (0.989)	98.2 (0.994)
Chen [19]	31 SCA 30 IPMN 28 MCN	CT	Radiomics LASSO Split sample	65.4 (0.683)	69.2 (0.817)	76.9 (0.869)
Nguon [20]	59 MCN 49 SCA	Endoscopic US	CNN Split sample	N/A	82.8 (0.88)	N/A
Yang [21]	63 SCA 47 MCN	CT	CNN RF Split sample	N/A	92.6 (0.98)	N/A

AUC, area under the curve; CNN, convolutional neural network; IPMN, intraductal papillary mucinous neoplasm; LASSO, least absolute shrinkage and selection operator; MCN, mucinous cystic neoplasm; RF, random forest; SCA, serous cystadenoma; SPN, solid pseudopapillary neoplasm; SVM, support vector machine; US, ultrasound.

Kuwahara [38]	27 LGD or MGD 23 HGD or invasive CA	EUS	CNN Crossvalidation	(0.560)	(0.940)	N/A

AUC, area under the curve; CA, cancer; CV, crossvalidation; EUS, endoscopic ultrasound; EV, external validation; HGD, high-grade dysplasia; IPMN, intraductal papillary mucinous neoplasm; LASSO, least absolute shrinkage and selection operator; LGD, low-grade dysplasia; MGD, moderate-grade dysplasia; RF, random forest; SVM, support vector machine.

Several radiomics and machine learning studies have focused on predicting the dysplasia grade in IPMNs (see Table 88.3). These studies, heterogeneous in design, differed in the type of imaging modality (CT, MRI, endoscopic US), type of cysts (inclusion or exclusion of main-duct IPMN, cases with invasive carcinoma), and validation methods. Despite their methodologic variations, these studies support the notion that radiomics with machine learning (AUC range 0.76–0.96) were superior to guideline-based clinical features (AUC range 0.56–0.84), and the combination of the two (AUC range 0.79–0.93) may offer the best performance in distinguishing between low-grade dysplasia and high-grade dysplasia or invasive carcinoma [23–29]. Such models could help refine the selection criteria for surgical resection, reduce unnecessary surgery, and tailor the surveillance interval based on the risk profiles of individual patients.

These preliminary studies have shown that machine learning trained solely on imaging data can achieve superior performance compared to current guideline-based features. However, imaging data only account for a fraction of the risk profile. The addition of clinical features, laboratory values, and cyst fluid analysis to the imaging data could further refine the risk assessment [30,31]. Springer et al. developed a machine learning *CompCyst* model that incorporated patient characteristics, imaging findings, and cyst fluid molecular analysis from 862 patients, and they used this model to predict pancreatic cyst type as well as appropriate management based on the underlying pathology [30]. In the validation cohort of 426 patients, 53 patients had benign cysts that could be safely discharged, 140 patients had mucin-producing cysts without invasive cancer or high-grade dysplasia that were appropriate for surveillance, and 152 patients had malignant cysts suitable for surgical resection. The machine learning model achieved superior accuracy in triaging patients into discharge and surveillance groups compared to current clinical management and could have avoided unnecessary surgery in 60% of patients in the validation cohort, while maintaining comparable sensitivity for identifying patients in whom surgery was indicated (91% vs 89%) [30]. Incorporation of multidimensional data in these machine learning models may be able to assist clinicians to better assess risk and optimize patient management.

Challenges and Future Directions

Artificial intelligence has the potential to revolutionize how we manage pancreatic cysts, but there are a few challenges limiting its translation into clinical practice. Firstly, most published reports are single-center retrospective studies with small sample sizes (less than a few hundred participants). Machine learning can be susceptible to overfitting, and the observations based on limited datasets may not be generalizable. It is estimated that the development of generalizable AI algorithms may require hundreds of thousands or even millions of cases to train [32]. This is problematic because curation of quality medical datasets is an expensive and labor-intensive process.

One potential solution is to apply natural language processing (NLP), a linguistic application of AI, to retrospectively identify patients with pancreatic cysts who may be eligible for research studies. Although our medical records have been in electronic format for at least the past 10–20 years, our clinical notes and radiology reports are still mostly composed of unstructured text. NLP can sift through these unstructured medical records to identify patients with pancreatic cysts [33,34] to help build large-scale longitudinal pancreatic cyst registries, which can provide the amount of data necessary to validate AI models. In addition, AI can be used to generate synthetic data to aid in model training. Generative adversarial networks (GANs) are composed of a pair of generator and discriminator deep networks, and through serial iterations, these paired deep networks are trained to produce realistic synthetic data [32]. However, it remains unclear whether these synthetic data are representative of the broad spectrum of variations that are present with real data.

Ideally, AI models should be validated on data from different institutions. Data acquisition and annotation should also be standardized across institutions to facilitate data compatibility. However, data sharing among institutions is often hindered by data security and patient confidentiality concerns. The National Cancer Institute and other organizations have initiated efforts to host central data repositories that allow member institutions to access the pooled resources from other institutions and strengthen inter-institution collaboration [35]. As an alternative to transferring patient data among various institutions, AI algorithms could be shared among institutions through federated learning [36]. With federated learning, patient data remain protected behind the firewall of each local institution. The AI model is trained and tested on each local dataset and sends feedback to update the central AI model [36]. This central AI model can leverage the power of each local dataset while alleviating concerns with data security.

Secondly, many publications, especially in the computer science literature, focus on comparing the performance of the study algorithm with the "state-of-the-art" benchmark. In order to be clinically relevant, AI performance should be compared to human experts, to evaluate if the AI would provide any additional value. These AI models also should integrate different sources and layers of clinical data to build comprehensive models (Fig. 88.4). Based on clinical presentation, past medical history, family history, and any known genetic mutations,

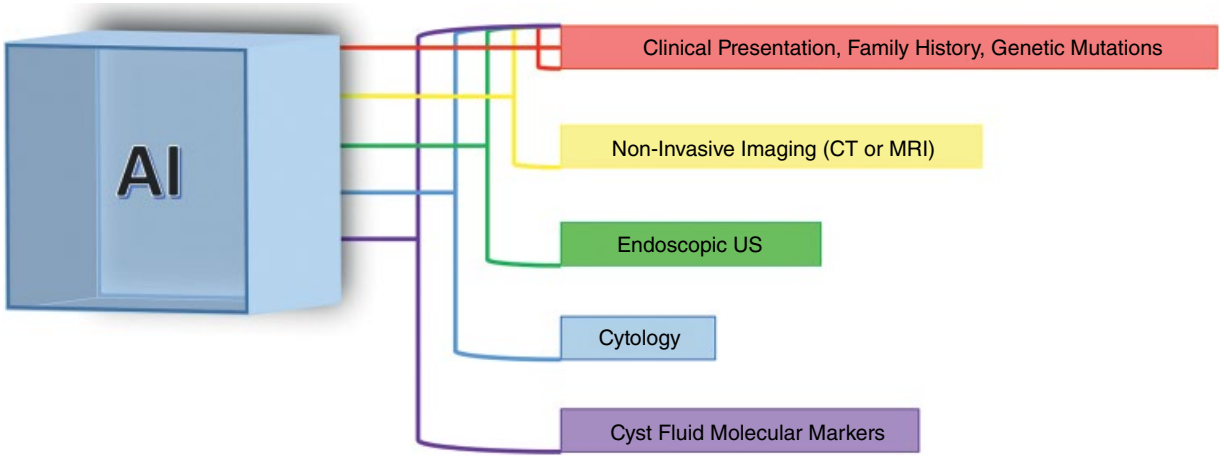

Figure 88.4 Artificial intelligence models have the opportunity to integrate various sources of data and provide clinical decision support during different stages of the patient's journey. Initial models may integrate clinical presentation, family history, and any known genetic mutations (red box) to assess the pretest probability of pancreatic neoplasm and determine if the patients require noninvasive imaging (yellow box) for further evaluation. The next layer of models will integrate both the clinical presentation and imaging data to determine if the patients require endoscopic ultrasound (green box). The final layer of models will integrate cytology (blue box) and cyst fluid molecular markers (purple box, if available) with the clinical presentation and imaging data to provide individualized patient management support.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

AI can determine subsets of patients who require noninvasive imaging (CT or MRI) for further evaluation. Additional AI models that incorporate imaging features and clinical features could determine who should proceed to endoscopic ultrasound and tissue sampling. Then a comprehensive model, analogous to the CompCyst model [30], should incorporate all clinical features, imaging features, and cyst fluid molecular markers, to provide clinical decision support in determining whether patients require surgical resection or periodic surveillance, or can be safely discharged. The validated AI models should be packaged with user-friendly interfaces and integrated seamlessly into clinical workflow, so that clinicians in both academic and private practice would be able to use these models and make a real impact in clinical care.

Thirdly, it is difficult to understand how AI makes decisions due to its black box nature. It can be problematic for clinicians to reconcile any disagreements between human and AI interpretation without understanding the rationale for the AI decision support. There has been active research to improve the transparency and explainability of the AI models and move from "black box AI" to "glass box AI" [37]. Glass box AI allows us to review the variables that are the main drivers for the AI prediction, allowing humans to ascertain whether these variables make biological sense. This may also help us gain better insight into which imaging or laboratory tests are high value, so that we can focus on accurate and cost-effective diagnostic tests for future patients.

Conclusion

Artificial intelligence has the potential to improve the detection of pancreatic pathology from medical images, which can lead to earlier pancreatic cancer diagnosis. It also has the potential to improve the diagnostic accuracy in pancreatic cyst classification and assessment of malignancy risk. These promising results must be validated in large-scale multi-institutional clinical trials. Future comprehensive AI models should integrate numerous sources of clinical data and can provide clinical decision support at various stages to determine the next most appropriate diagnostic test or management strategy.

[3] *University of Colorado Cancer Center, University of Colorado Anschutz Medical Campus, Aurora, CO, USA*

Introduction

Pancreatic cystic neoplasms (PCNs) are common. A recent prospective study showed a prevalence of pancreatic cystic lesions of 49.1% in the general population [1]. Some PCNs are considered benign, for example serous cystic neoplasms of the pancreas, as they present almost no risk for progression to cancer [2]. In contrast, other PCNs, like intraductal papillary mucinous neoplasms (IPMNs) and mucinous cystic neoplasms (MCNs), can progress to cancer [3].

The clinical management of PCNs is extremely challenging for two primary reasons. First, even though their biologic behavior and histologic characteristics are different, these lesions are hard to differentiate using conventional radiology. Some studies suggest that the diagnostic accuracy of PCNs, even at tertiary, high-volume referral centers, is no higher than 60–70% [4]. More recently, endoscopic ultrasound (EUS) with fine needle aspiration (FNA) has been proposed as a valid method of differentiating mucinous (e.g., IPMNs and MCNs) from nonmucinous (e.g., SCN) neoplasms. The presence of a CEA concentration $\geq$192 ng/mL in the cystic fluid has an accuracy of 75% in diagnosing mucinous lesions [5]. However, even assuming that differential diagnosis between mucinous and nonmucinous lesions is possible, determination of the level of dysplasia (or cancer) associated with the lesion and the need for, and proper timing of, surgical resection is rarely possible preoperatively. Since 2006, several scientific society guidelines have been published to try to guide the management of cystic lesions of the pancreas. However, we are not yet able to reliably identify the ideal timing for surgical intervention.

High-grade dysplasia (HGD) in mucinous cystic neoplasms should be considered the optimal target for surgical resection. However, considering that we don't have methods to reliably identify this level of progression, an unsolved question is: is it better to overtreat or undertreat? For example, is it better to resect some low-grade dysplasia (LGD) in order to catch the maximum number of HGD lesions or to minimize surgery in LGD lesions, at the risk of missing some HGD lesions? This question has no evidence-based answer. However, in the authors' opinion, the morbidity and mortality risk of pancreas cancer outweighs the risk of surgery in many carefully selected patients. Therefore, the risk of missing a lesion with HGD or a cancer is carefully weighed. In this chapter, we will focus our attention on the oncologic surgical management of mucinous cystic tumors of the pancreas.

Principles of Oncologic Resection in Mucinous Tumors of the Pancreas

Mucinous tumors of the pancreas should be treated surgically when there is a suspicion or proof of HGD and/or malignancy. For this reason, oncologic resections are most commonly performed.

While parenchyma-sparing procedures have been proposed for the treatment of mucinous neoplasms of the pancreas, the authors' opinion is that this approach was more appropriate in the past when many more low-risk lesions were being resected. Previously, surgery was often offered in cases of "innocent" appearing lesions and there was less knowledge of the biology of these diseases.

In the case of IPMNs, surgery cannot be considered a diagnostic tool or a strategy to discontinue surveillance. Even in cases of a single branch duct (BD)-IPMN, there is a risk of future development of other IPMNs in the pancreatic remnant and an increased risk of pancreatic cancer. Therefore, surveillance should be continued after resection. This differs from MCNs, where radical excision of a noninvasive lesion corresponds with cure.

Surgical Indications

IPMNs

IPMNs are classified morphologically into three different groups. In branch duct IPMNs (BD-IPMNs), the disease macroscopically affects "only" the side branches of the pancreas. These lesions are frequently multiple and characterized radiologically by communication with the main pancreatic duct. The risk of malignant transformation is lower than the other types. In published series, this risk ranges from 11% to 30% [3]. Main-duct IPMNs (MD-IPMN) are IPMNs exclusively involving the main duct. Mixed-type IPMNs (MT-IPMN) exhibit involvement of both the main duct and branch ducts. When the main pancreatic duct is involved, the risk of malignant progression seems to be higher, with reported rates between 36% and 100% [3].

For this reason, in cases of MD-IPMNs or MT-IPMNs, surgical resection should be considered in patients fit for surgery. There is broad agreement that surgery is indicated for main pancreatic duct (MPD) dilation over 10 mm, but this is debated for MPD dilation between 5 and 10 mm [6,7]. Recent studies emphasize the importance of a surgical evaluation starting at 5 mm diameter of the MPD. These data from surgical series have shown a correlation between MPD dilation over 5 mm and the risk of IPMNs associated with HGD and/or invasive cancer [8-10].

For BD-IPMN, the diameter of the cyst (> of 3 or 4 cm) was historically considered the main indication for surgery [11,12]. More recently, the role of measurements alone has been reevaluated and found to be less important [8]. For this reason, the new evidence-based European guidelines on cystic tumors of the pancreas consider the diameter of the cyst measuring over 4 cm to be only a relative indication for surgery [6]. These guidelines define absolute indications for surgery as the presence of cytology positive for malignancy/HGD, solid masses, jaundice caused by the lesion, enhancing mural nodules (≥5 mm), and MPD dilation over 10 mm. Relative indications for surgery are fast growth of the cyst (≥5 mm/year), serum Ca 19.9 levels greater than 37 U/mL, dilation of the MPD between 5 and 10 mm, cyst diameter greater than 4 cm, enhancing mural nodules (<5 mm), and symptomatic lesions (i.e., IPMN-related acute pancreatitis or new-onset diabetes) [6]. The introduction of the concept of "relative indications" in the European evidence-based guidelines on cystic tumors of the pancreas is innovative because it gives the clinician discretion to personalize the management based on the patient's characteristics (i.e., expectancy of life or performance status).

MCNs

In the past, all patients with MCN were recommended for resection. However, beginning in 2013 and more recently in 2018, the European guidelines on cystic tumors of the pancreas introduced the possibility of surveillance in patient with small (<4 cm) MCNs [6,12]. The safety of this approach has been supported by retrospective data [13,14]. In general, in cases of suspected malignant MCN, a "radical" operation should be performed. A distal pancreatectomy with splenectomy is the most common operation performed, as the usual location of this disease is the body and/or tail of the pancreas. A Whipple procedure is recommended for surgical treatment of pancreatic head lesions.

Oncologic Resection of IPMN and MCN

Given the topic of this chapter, our attention will be focused on "radical" resection in cases of suspected invasive disease. As a general consideration, we must acknowledge that if surgery for IPMN and MCN is ideally done only in cases of suspected invasive cancer and/or HGD, there is a very limited role for local resection. Although the general approach to open procedures is described below, these resections can also be accomplished laparoscopically and robotically.

Preoperative Work-up

Radiological diagnosis and staging guide surgical intervention in patients affected by IPMNs and MCNs. Preoperative cross-sectional imaging (CT scan and/or MRI) should be available. Many patients undergo EUS + FNA. Preoperative histologic diagnosis can be useful but is not mandatory to proceed with surgery. Other diagnostic modalities can be useful in select cases. For example, in IPMN cases with whole pancreas duct dilation, a preoperative pancreatoscopy can help define the extent of the disease in the main duct [15]. A full evaluation of operative risk is mandatory before pancreatic surgery. This is doubly important in cases where surgery is being offered for IPMNs and MCNs, given the absence of a clear diagnosis of cancer in many of these cases.

Considering the complexity of these cases, a review at a dedicated pancreas multidisciplinary conference is, in our opinion, recommended [16].

Pancreaticoduodenectomy (Whipple procedure)

An open pancreaticoduodenectomy can be done with a midline incision (method preferred by the authors) or a subcostal incision. The first part of the operation is dedicated to excluding the presence of radiologically undetected metastatic disease. The liver, peritoneum, and mesentery are carefully examined for the presence of undetected metastasis. If suspicious lesions are detected, a frozen section histologic analysis is required.

Once the presence of visible metastatic tumor is excluded, a full Kocher maneuver (extending to the aorta) is performed. This maneuver enables the surgeon to better evaluate the mass in anatomic relation to the superior mesenteric vessels. In the case of suspected superior mesenteric artery (SMA) involvement, the aortic origin of the vessel can be identified and an artery first approach can be performed.

After completing the Kocher maneuver, the lesser sac can be assessed through dissection of the gastrocolic ligament. This gives the surgeon the ability to assess the body and neck of the pancreas. The superior mesenteric vein can be identified below the pancreatic neck and assessed for tumor involvement. In the event of vein involvement, control of the vein can be achieved below the mesocolon, in the mesenteric root using a mesenteric approach, to assess the possibility of vein reconstruction [17].

After this step, the hepatoduodenal ligament is dissected. The gallbladder is removed (*en bloc* with, or separate from, the main specimen). A hepatoduodenal ligament lymphadenectomy is then performed *en bloc* with visualization of the left and right hepatic arteries, common and proper hepatic arteries, gastroduodenal artery, hepatic portal vein, and distal bile duct. The dissection can be easily extended to expose the celiac trunk, depending on surgeon preference. The distal bile duct is divided. We recommend a frozen section histologic analysis of the margin. The right gastric artery is ligated and divided. To exclude the presence of critical celiac trunk stenosis, the gastroduodenal artery (GDA) is clamped and the flow in the hepatic artery is evaluated. The GDA is then ligated and divided.

At this point, the duodenum is divided 1.5 cm distal to the pylorus (for pylorus-preserving procedures) or an antrectomy is performed (for nonpylorus-preserving procedures). A tunnel below the pancreatic neck is then created and the pancreas neck is transected. In case of venous involvement at this level by the tumor, this tunnel is made distal in the pancreas body and the pancreas is divided at the left aspect of the superior mesenteric vein. The jejunum is then transected approximately 15 cm distal to the ligament of Treitz and the ligament is fully mobilized. At this point, the head of the pancreas is dissected out from the superior mesenteric portal vein with selective suture ligation of the venous branches. Finally, the SMA margin is taken following 180° full clearance of the right side of the artery and selective suture ligation of the pancreaticoduodenal arteries. The specimen is then removed with *en bloc* resection of, at a minimum, lymph node stations 5, 6, 8a, 12b, 12c, 13a, 13b, 14, 17a, and 17b. The aortocaval lymph nodes may also be removed as a staging measure.

The reconstruction after resection can be performed using different techniques. Normally, a trans-mesocolic pancreatojejunostomy (duct-to-mucosa is the authors' preference) is created on the proximal jejunal loop. Distally, an end-to-side hepaticojejunostomy (the authors prefer using 4-0 or 5-0 absorbable, interrupted suture) is performed. Finally, an antecolic duodeno- or gastrojejunostomy is performed.

Distal Pancreatectomy

An abdominal exploration, as described in the previous section, is performed at the beginning of the operation. The gastrocolic ligament is divided and the lesser sac is explored. The splenic flexure of the colon is fully mobilized. In cases where the lesion is in proximity to or contact with the superior mesenteric vein, a Kocher maneuver is performed to better control possible bleeding during the dissection. The origin of the splenic artery from the celiac trunk is identified. As part of this maneuver, a lymphadenectomy of stations 8a and 9 is performed. This is done both for oncologic reasons and to clarify anatomy [18]. The splenic artery is controlled, ligated, and divided.

If the lesion is not in contact with the superior mesenteric portal vein, a tunnel is created below the pancreatic neck and the pancreas is divided. Notably, this step is performed last in operations for lesions close to the superior mesenteric portal vein. The pancreatic neck is generally transected using a stapler device. Stapler reinforcement is not mandatory, given the lack of evidence for reinforcement reducing the incidence of pancreatic fistula [19]. In cases where the pancreatic parenchyma is very thick or when a resection should be extended towards the pancreatic head, the parenchyma is transected with scalpel or electrocautery. The main pancreatic duct is identified and closed with nonabsorbable suture. The transected parenchyma is then closed using interrupted non-absorbable suture. The short gastric vessels are then ligated and divided. The spleen is

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

mobilized from the retroperitoneum *en bloc* with the body and tail of the pancreas.

At this point, the splenic vein is divided and the specimen removed *en bloc* with lymph nodes stations 10, 11, and 18 [18]. For lesions more distal in the pancreas, a portion of the pancreatic body can be preserved by moving the parenchymal line of resection distally, as long as there is adequate margin. A radical antegrade modular pancreatosplenectomy (RAMPS) approach can be performed as an alternative, especially in cases with clear signs of invasive cancer [20].

Total Pancreatectomy

Total pancreatectomy is not often performed for IPMNs and almost never used for MCNs (with the possible exception of locally advanced disease). A total pancreatectomy can be performed when there is extensive main duct involvement in IPMN or when it is not possible to achieve a margin free of cancer or high-grade dysplasia after partial pancreatectomy [6]. The technique used is a combination of the distal pancreatectomy and the Whipple procedure, as described above.

Treatment of Borderline Resectable or Locally Advanced Disease

For malignant MCNs, no definitive data are available regarding the use of neo-adjuvant treatment. For invasive IPMNs, we follow the same indications as for pancreas cancer. At our institution, a surgical exploration is indicated in every patient with radiologic response or stable disease after neo-adjuvant treatment, especially when there is a biomarker response, regardless of the vessels involved. The technical aspects of vessel management have been described previously [21,22].

Use of Intraoperative Pancreatoscopy

The role of frozen section analysis of the resection margin in the prevention of recurrence in the pancreas remnant in IPMNs patients is debated [23]. This is due to the possibility of skip lesions being present in the pancreatic remnant that cannot be detected by a margin analysis. Recently, intraoperative pancreatoscopy has been proposed as a tool to individualize the extent of resection in MD-IPMN patients [24]. However, the utility of this modality still needs to be validated in prospective studies.

Results of "Oncologic" Surgery for IPMNs and MCNs

Even if invasive IPMNs and pancreatic cancer share many biologic aspects, the long-term prognosis of patients with invasive IPMN who undergo resection seems to be better than that of patients with pancreas cancer (five-year overall survival 31.4% vs 12.4%) [25]. The use of adjuvant therapy for invasive IPMN has the same indications as in pancreas cancer. However, based on retrospective studies, the role of adjuvant treatment seems to be debatable for invasive IPMNs in the case of N0 disease [26].

Invasive MCNs are associated with an even better prognosis than invasive IPMNs. In a recent large single-institution experience, the disease-specific survival at 10 years of patients who underwent surgery for MCNs was significantly higher than for those who underwent surgery for invasive IPMNs (79.6% vs 27.2%). Despite the lack of clear supporting data for this practice in invasive MCNs, the same adjuvant approach as for pancreas cancer is generally used.

Conflict of interest

Dr. Del Chiaro has been awarded an industry grant (Haemonetics, Inc) to conduct a multi-center study to evaluate the prognostic implications of TEG in pancreas cancer.

Dr. Del Chiaro is a co-PI of a sponsored Boston Scientific study on the use of intra-operative pancreatoscopy in IPMN's patients.

Introduction

Pancreatic cystic neoplasms (PCNs) are a diverse and genetically unrelated group of neoplastic pancreatic diseases which include the mucinous neoplasms—intraductal papillary mucinous neoplasia (IPMN) and mucinous cystic neoplasia (MCN)—as well as serous cystic neoplasia (SCN), solid pseudopapillary neoplasia (SPN), and cystic neuroendocrine tumors (cNET) [1]. Their shared tendency to macroscopically form cystic structures belies their distinct underlying molecular compositions. More importantly, these distinct clinical entities differ in their evolutionary propensity to progress from benign to malignant disease, which has enormous implications for management [2]. As PCNs are mainly diagnosed incidentally in a premalignant stage and commonly asymptomatic, the primary goal of therapy is the timely prevention of invasive cancer [3]. Thus the indications, extent, and approach of surgical treatment are guided by the attributes of each cyst's biology.

In this chapter, we stress the importance of oncologic surgical principles for lesions that suggest high-grade dysplasia or malignancy. The value of pancreas parenchyma-sparing techniques, particularly enucleation and central pancreatectomy, are highlighted for certain cyst configurations which indicate an early stage with potentially progressive dynamics. Focusing on laparoscopic and robotic approaches, we discuss the implications of cyst biologies on surgical strategy, reflect on the conceptual framework of minimally invasive surgery for pancreatic resections, and summarize the current evidence. Collectively, we deliberate on how these modern techniques for PCN surgery can address the quandary of balancing survival benefits with possible sequelae of overtreatment (Table 90.1).

Specific Implications of Cystic Neoplasms for Surgical Treatment

From the surgeon's perspective, resections of PCNs demand specific considerations. As a universal concept, the risk of malignant transformation needs to be balanced with potential complications along with long-term endocrine and exocrine pancreatic insufficiency. Here, a formal oncologic resection and parenchyma-sparing surgical techniques stand against surveillance. If high-grade dysplasia or a malignant disease stage are suspected, oncologic resections with a radical margin and lymphadenectomy (with splenectomy during distal or total pancreatectomy) should be performed independent of PCN etiology [1]. However, the preoperative determination of epithelial dysplasia grade (low-/intermediate-grade vs high-grade vs malignancy) and prediction of future cancer from, at diagnosis, benign neoplastic lesions are challenging and vary depending on the specific cyst biologies. For instance, the probability of IPMNs transforming into malignancy is substantially higher if the pancreatic main duct (MD) is affected (MD-IPMN and mixed-type [MT]-IPMN) compared to isolated branch duct (BD) involvement [4,5]. Furthermore, the risks of both focal-to-multifocal cyst evolution and concomitant pancreatic adenocarcinoma (PDAC) are increased which suggests the proposition that IPMN reflects vulnerability of the whole pancreatic gland through an underlying genetic field defect [6]. Consequently, experts have elaborated on a potential role of preventive total pancreatectomy for selected patients (no established indications currently) [7,8].

Details of the current PCN guidelines with integrated indications of surgical treatment are beyond the scope of this chapter (e.g., differentiation of IPMN characteristics into "high-risk stigmata" and "worrisome features" for risk stratification) [4,5]. Briefly, due to a considerable risk of

Table 90.1 Considerations for modern surgery of pancreatic cystic neoplasia.

Keynotes

- Pancreatic cystic neoplasms are amenable to minimally invasive pancreatic surgery, if laparoscopic or robotic approaches *do not compromise* the indicated extent of resection and safety.
- Oncologic resections are critical for high-grade dysplasia and invasive cancer.
- Pancreas parenchyma-sparing techniques, such as enucleation and central pancreatectomy, are suitable for early-stage lesions and efficient in preventing pancreatic insufficiency (endocrine and exocrine).

high-grade dysplasia or malignancy, an oncologic resection is indicated generally for all MD- or MT-IPMNs (MD dilation ≥5 mm according to the 2018 European guidelines, MD dilation ≥10 mm according to the 2017 IAP/Fukuoka guidelines), BD-IPMNs with at least one high-risk stigma and MCNs ≥4 cm with suspicious radiologic features [4,5]. For BD-IPMNs with a suggested risk of benign-to-malignant progression without signs of high-grade dysplasia or malignancy (worrisome features but no high-risk stigmata), parenchyma-sparing techniques such as central pancreatectomy and enucleation are considered sufficient alternatives (Tables 90.2 and 90.3) [4].

However, the finite accuracy of IPMN grading is unknown before the completed histomorphologic investigation of the surgical specimen. For SPNs, as they rarely metastasize even given their malignant potential, parenchyma-sparing procedures are also proposed to be adequate [9]. In contrast, lymphadenectomy should be performed for resections of cNETs (surgical indication if ≥2 cm in diameter) [4]. Finally, SCNs are benign lesions which only require a nononcologic resection if crucial surrounding structures (e.g., mesoportal venous system) are mechanically compressed [4].

Table 90.3 Indications for pancreas parenchyma-sparing resections for pancreatic cystic neoplasms (PCNs).

Candidacy for pancreatic enucleation	Candidacy for central pancreatectomy
PCN without main duct involvement and low potential for high-grade dysplasia or malignancy	PCN with low potential for high-grade dysplasia or malignancy
BD-IPMN without high-risk stigmata	BD-IPMN without high-risk stigmata but close main duct proximity
SPN	SPN with close main duct proximity
SCN, if essential pancreas-surrounding structures are compressed	SCN with close main duct proximity, if essential pancreas-surrounding structures are compressed

BD-IPMN, branch-duct intraductal papillary mucinous neoplasia; SCN, serous cystic neoplasia; SPN, solid pseudopapillary neoplasia.

Conceptual Framework of Minimally Invasive Pancreatic Surgery

Laparoscopic surgery, the first technique developed for a minimally invasive operation, has revolutionized surgical care, especially for procedures such as appendectomies and cholecystectomies. The laparoscopic approach can effectively reduce the trauma of surgical access (smaller wounds with decreased systemic inflammation/stress response along with improved cosmetics compared to laparotomy) and consequently lead to a shorter length of hospital stay (enhanced recovery) [10]. Moreover, patients experience a decreased prevalence of postoperative incisional hernias and fewer intraabdominal adhesions [11]. Given the compelling data and successes, minimally invasive techniques have been applied

Table 90.2 Available trials with high-level evidence from randomized controlled data on minimally invasive pancreatic surgery.

Trial ID	Year of publication	Country	Centers	Approach	Patients analyzed
Distal pancreatectomy					
LEOPARD	2019	Netherlands	Multicenter	Laparoscopic/robotic vs open	42/5 vs 55
LAPOP	2020	Sweden	Single center	Laparoscopic vs open	29 vs 29
Pancreatoduodenectomy					
PLOT	2017	India	Single center	Laparoscopic vs open	32 vs 32
PADULAP	2018	Spain	Single center	Laparoscopic vs open	34 vs 32
LEOPARD-2	2019	Netherlands	Multicenter	Laparoscopic vs open	50 vs 49

to procedures of higher technical complexity characterized by increased intraabdominal trauma.

During pancreatic surgeries, major veins and arteries are encountered, requiring delicate technical maneuvers. Furthermore, during a pancreatoduodenectomy (PD) and total pancreatectomy, intestinal reconstruction is performed with a series of anastomoses (gastrojejunostomy and hepaticojejunostomy; pancreaticojejunostomy during PD). In 1994, Gagner and Pomp reported the first case of laparoscopic PD (for pancreas divisum-related chronic pancreatitis) and Cuschieri published his initial laparoscopic pancreatic surgery experience including PD, distal pancreatectomy (DP), and insulinoma resection [12,13]. Robotic pancreatic resections, which are characterized by superior manual dexterity and optics, were pioneered by Giulianotti et al. in 2001 [14]. The benefit of the minimal access approach described above for laparoscopic surgery applies to robotic operations.

Intriguingly, prognostic and epidemiological evidence specific to PCNs may favor a minimally invasive approach for a set of patients with its proposed clinical benefits. The majority of PCNs are detected in a premalignant disease stage which suggests surgical treatment as an opportunity for prophylaxis. As opposed to patients with PDAC, patients with detected PCNs are frequently cured with resection and tend to be younger at time of diagnosis, making a long-term high quality of life particularly desirable. This translates into the premise to deliver surgery with the least possible morbidity. However, the underlying PCN biology specifically needs to be addressed and, if indicated, it is imperative that a minimally invasive resection is performed with the oncologic principles similar to the open approach. For technically complex and radical resections with intestinal reconstructions, the impact of reduced surgical access trauma on outcomes is beneficial [15].

Minimally Invasive Distal Pancreatectomy

Distal pancreatectomy comprises resection of the pancreatic body and tail with simultaneous splenectomy for oncologic resections. The laparoscopic approach has been widely applied for DP and various single- and multicenter case series have demonstrated similar perioperative outcomes with a shorter hospital stay when compared to open DP [16]. A metaanalysis of 29 observational studies confirmed superiority of laparoscopic DP for hospital stay (mean difference 4.6 days), time to first oral food intake (mean difference 1.3 days), and blood loss (mean difference 308 mL) while rates for overall morbidity (37%), postoperative pancreatic fistula (POPF) (22%), and 30-day mortality were similar (0.4% vs 1.1%) [17]. In this study with a pooled laparoscopic DP cohort of 880 patients, 49% underwent resection for PCNs. For robotic DP, several reports indicated equivalent perioperative mortality, morbidity, and length of hospital stay compared to laparoscopic DP, with similar advantages over the open approach for selected patients [18,19]. In one of the observational studies, robotic DP was associated with a lower rate of conversion and splenic preservation, but longer duration of surgery than laparoscopic DP [19].

Recently, data from two randomized controlled trials (RCTs) designed to compare minimally invasive vs open DP were presented [20,21]. In the multicenter LEOPARD trial, 47 patients underwent minimally invasive DP (42 laparoscopic, five robotic) and 55 open DP. With the primary outcome being postoperative time to functional recovery, the trial demonstrated a benefit of two days with the minimally invasive approach (4 vs 6 days) along with a median two-day shorter hospital stay (6 vs 8 days). No mortality and a similar major complication rate (23% vs 38%) were observed in the minimally invasive cohort (spleen preserved in a similar fraction of patients, 45% vs 50%) [20]. Improved time to functional recovery (4 vs 6 days), shorter hospital stay (5 vs 6 days) and comparable major morbidity rates (4% vs 8%) were confirmed in the single-center Swedish LAPOP trial which enrolled 29 patients in each group of laparoscopic and open DP (overall 55% of patients with PCN) [21]. Interestingly, the major complication rates were substantially lower in the LAPOP than in the LEOPARD trial (Clavien-Dindo grade ≥IIIA, overall 6% vs 31%) and a conversion to open rate of 3% compared to 9%.

Minimally Invasive Pancreatoduodenectomy

Pancreatoduodenectomy is characterized by a complex *en bloc* resection and intestinal reconstruction with three anastomoses, thereby enhancing technical complexity compared to DP. For laparoscopic PD, early data by Kendrick and Cusati demonstrated safety in their initial experience of 65 consecutively selected patients with only one 30-day/in-hospital mortality [22]. Case–control matched single-center series revealed postoperative mortalities between 0% and 7% [23].

Since 2017, results of four conducted RCTs have been published investigating laparoscopic vs open PD. The PLOT [24] (India, 32 vs 32 patients) and PADULAP [25] (Spain, 34 vs 32 patients) trials both had a monocentric design and laparoscopic PD was restricted to two and one highly experienced surgeons only, respectively. In the PLOT trial, median hospital stay almost halved in the laparoscopic group (7 vs 13 days) with equal rates of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

complications (overall 28%) and postoperative mortality (one out of 32 patients in each group). Although a shorter length of hospital stay was also observed in the PADULAP trial, patients were not discharged until a median of 13.5 days (vs 17 days). None of the 34 patients died within 90 days after laparoscopic pancreatoduodenectomy. Encouraging safety was also demonstrated in the large multicenter MITG-P-CPAM trial (China, 328 vs 328 patients) with a 90-day postoperative mortality of 2% [26]. Notably, all participating surgeons from 14 centers had performed at least 104 laparoscopic PDs. However, although significantly shorter, length of hospital stay had an arguably small effect size of just one day benefit in the laparoscopic PD group (15 vs 16 days).

In contrast, the multicenter LEOPARD-2 trial (Dutch Pancreatic Cancer Group, 50 vs 49 patients) was prematurely terminated due to a mortality rate of 10% in the laparoscopic PD group (vs 2% after open PD) [27]. The participating eight surgeons from four centers had completed a specifically designed laparoscopy training program and had experience of at least 20 cases (during training, 90-day mortality rate 3.5%) [28]. A side analysis of 38 patients from the LEOPARD-2 cohort aimed to compare the systemic inflammatory response within 96 hours postoperatively through serum IL-6, IL-8, and CRP levels and found no differences [29].

Finally, data from a metaanalysis further indicate that a profound learning curve and high operative volume are needed to achieve results with potentially modest benefits [30].

To perform minimally invasive PD with improved technical feasibility, robotic technologies are gaining traction internationally [31]. In four independent single-center series of robotic PD which included between 96 and 500 patients, perioperative safety was demonstrated with postoperative 90-day mortalities between 2.1% and 3.6% [32–35]. With regard to complications, case–control (open PD) matched studies resulted in noninferior rates of POPF and anastomotic insufficiencies. In contrast, data suggest a shorter length of hospital stay and fewer wound infections [34,35].

Recently, delicate surgical refinements for a radical dorsal margin (retropancreatic nerve plexus with TRIANGLE resections, periadventitial dissection of major arteries) have been demonstrated to be feasible, exploiting the 10× optical zoom and seven degrees of freedom of the robotic instruments, so that steps of robotic resections increasingly resemble the open procedure [36]. Nevertheless, importantly, it has been recognized that skill and favorable perioperative outcomes come at the cost of an extensive learning curve.

A recent systematic review compared robotic with laparoscopic learning curves and found similar case numbers were required to achieve a plateau in operative time for both PD (37 vs 34 cases) and DP (21 vs 25 cases) [37]. Although case volume and reported experiences in an increasing number of institutions are promising, quality evidence from RCTs that recruited patients with robotic pancreatic resections compared to open or laparoscopic resections is unavailable, but trials are ongoing (e.g., EUROPA trial).

Minimally Invasive Parenchyma-sparing Pancreatic Resection

Parenchyma-sparing pancreatic resections include enucleation, central pancreatectomy, and uncinate process resections (referred to as inferior pancreatic head resection). They are performed for presumed noninvasive PCNs to maximize preservation of functional endocrine and exocrine tissue (indications summarized in Table 90.3) [38]. Data from open resections emphasize its efficacy. A metaanalysis on enucleation for BD-IPMN resection from 16 retrospective studies with 293 patients determined postoperative endocrine dysfunction in 1% and exocrine insufficiency in 7% of the patients, both substantially lower than after formal resection (38% and 30%, respectively) [39].

Reflections on conversion to formal resection and surgical technique were reported in a large retrospective single-center series from Heidelberg [40]. In this study, 115 patients underwent laparotomy with the intent of enucleation for BD-IPMNs with less than 3 cm in cyst diameter. The intraoperative decision to convert to a formal resection was made in approximately one-third of the patients, while 87 enucleations (59% located in the pancreatic head or uncinate process, no enucleations for tail lesions) were performed in 74 patients with no perioperative mortalities. Common causes of conversion were a larger than expected cyst size and multifocal appearance. Subsequently, cystic main duct involvement was detected in 56% of the converted patients on final pathology, whereas all enucleated patients showed cyst-free margins at the BD-IPMN specimen (confirming an uninvolved main duct). Compared to the converted patients, enucleation resulted in a shorter hospital stay (10 vs 14 days), lower endocrine dysfunction (2% vs 57%), decreased exocrine insufficiency (11% vs 46%), and a similar POPF rate (27%). Technically, the dissection was performed primarily bluntly with ligation of adherent vascular or ductal structures. The authors relied on routine intraoperative fresh frozen histology to rule out high-grade dysplasia or malignancy, which would have led to conversion [40].

Assessing open central pancreatectomy, a large metaanalysis (56% of patients had PCNs) with pooled 1305 patients from 50 studies resulted in postoperative endocrine and exocrine dysfunction in 4% and 5% (both lower than after DP or PD), verifying its proposed

efficacy. While perioperative mortality was only 0.5%, POPF developed in 35% of the patients (higher compared to DP and PD) and contributed to an overall postoperative morbidity of 51% (higher compared to DP, but no difference from PD) [41]. Further analyzing and elaborating on potential advantages and risks, Lee et al inferred from their case–control study that central pancreatectomy is vindicated as an alternative to DP when a considerable pancreatic tail volume can be preserved [42]. Patients should have a high performance status to enhance postoperative recovery.

The feasibility of minimally invasive parenchyma-sparing pancreatic resections has been suggested by small single-center case series. Dedieu et al. analyzed outcomes in 23 consecutive patients with laparoscopic enucleation indicated for pancreatic neoplasms (insulinoma or PCNs). Uncertainty in localizing the tumor without palpation led to conversion to open surgery in two patients [43]. While in this series one patient died within 30 days postoperatively, a study by Mabrut et al. demonstrated no mortality after 21 laparoscopic enucleations [44]. For laparoscopic central pancreatectomy, Senthilnathan et al. indicated feasibility in 14 selected patients and reported no mortalities, with a POPF grade B in 14% of the patients as the only major morbidity. For Roux-en-Y anastomosis of the distal gland to the jejunum, the authors adjusted their technique according to the gland texture and duct size; for a soft gland with an undilated duct, "dunking" was performed whereas for a firm gland with a dilated duct, a duct-to-mucosa technique was preferred [45].

In a case–control study comparing laparoscopic to open central pancreatectomy, Song et al. demonstrated no postoperative 30-day mortalities for both approaches, and a longer operation time (350 vs 270 min) but shorter length of hospital stay (14 vs 22 days) after laparoscopic resection (26 vs 14 patients) [46].

Surgeons are also utilizing the robotic platform with its improved flexibility through the EndoWrist- instruments for parenchyma-sparing pancreatic resections. In 2015, Shi et al. retrospectively compared perioperative outcomes in patients who underwent robotic vs open enucleation (26 vs 13 patients) for insulinoma or PCNs. In addition to no endocrine and exocrine insufficiency with the robotic approach, they reported less trauma, shorter operation time, less blood loss, faster wound recovery, and unchanged events of POPF (23% grade B, no grade C, all patients received somatostatin) [47]. Technically, enucleation was mainly performed with a robotic ultrasound scalpel (alternatively, electronic hook or monopolar curved scissors) and, for securely localized tumors, the surgeon placed a suture through the lesion as an anchor for refined traction. The authors described how the amplified vision at the robotic console enabled direct ligation of the proximal branch duct at the resection margin after enucleation of an BD-IPMN and proposed that the superior precision granted by the robotic system may therefore decrease rates of POPF [48].

In an independent series where propensity-score matching was applied (robotic vs open enucleation of pancreatic neuroendocrine tumors smaller than 2 cm), similar frequencies between the two cohorts of major complications and POPF validated feasibility and safety [49]. For robotic central pancreatectomy, a recent metaanalysis of 12 observational studies with 265 patients suggested a 0.5% postoperative mortality, a major morbidity rate of 9.4% and a clinically relevant POPF in 42.3% of the patients [50]. Endocrine insufficiency occurred in only 0.3% of the patients, confirming efficacy of the surgical technique.

In summary, parenchyma-sparing pancreatic resections are highly effective to prevent endocrine and exocrine pancreatic insufficiency. Experienced surgeons demonstrated comparable outcomes of laparoscopic and robotic compared to open resections. A considerable limitation is that palpation is not possible due to the lack of haptic feedback of minimally invasive tools, which complicates identification of tumors, making high-resolution preoperative imaging and anatomic landmarks critical. Potential advantages are improved precision through a magnified view, decreased surgical access trauma, and enhanced recovery.

Conclusion

Pancreatic cystic neoplasms are amenable to minimally invasive pancreatic resections, if the indicated extent of resection can be achieved without compromises. Guided by the specific cyst biology, surgical techniques include oncologic as well as nononcologic, parenchyma-sparing methods such as central pancreatectomy and enucleation particularly for certain BD-IPMNs. The laparoscopic platform is established for DP and has been proven in RCTs to accelerate functional recovery. Regarding PD, the robotic approach is promising to overcome the limited flexibility and dexterity of laparoscopic instruments to perform a safe and noninferior operation. Parenchyma-sparing methods are highly effective to preserve endocrine and exocrine pancreatic function. As such, enucleation should be considered as a suitable procedure for BD-IPMNs without high-risk stigmata, allowing risk elimination of lesion-specific malignancy. Although feasible as demonstrated by experienced surgeons, clinical trials are important to validate noninferiority compared to open parenchyma-sparing pancreatic resections and identify milestones of procedure-specific learning curves.

Future innovations in robotics, computation, and imaging for improved precision, assistance, and intraoperative PCN localization may further accelerate the benefit of minimally invasive PCN surgery.

Robotic-assisted Resection of Cystic Neoplasms

Kimberly Kopecky and Jin He

Department of Surgery, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Introduction

The evolution, adoption, and routine use of robotic platforms to advance the field of pancreatic surgery have evolved over the past 18 years since Melvin et al. [1] first published the case of a robotically resected pancreatic neuroendocrine tumor. Since then, several international case series have supported the safety and equivalency of surgical outcomes in highly selected patients operated on by surgeons experienced in both hepatobiliary and minimally invasive surgical techniques [2–13]. Review articles, metaanalyses, and international consensus guidelines have summarized multiinstitutional outcomes and arrived at similar conclusions [14–21]. Despite these meaningful advances and comparable outcomes, less than 10% of all pancreatic surgery is performed robotically, even at high-volume academic centers [7,16].

Robotic pancreatic surgery offers several key advantages when compared to open and laparoscopic surgery. Three-dimensional magnified optics enhance intraoperative visualization [14,15], the camera itself has increased stability compared to traditional laparoscopy and is controlled by the operating surgeon, and the use of indocyanine green fluorescence improves the visualization of biliary anatomy. EndoWrist® instruments allow increased degrees of operative freedom, making technically challenging dissections and anastomoses possible, and the lack of tactile feedback does not limit operative capability [15,22,23]. As with other minimally invasive approaches, wound complications, including wound infections and incisional hernias, are significantly minimized with use of the robotic platform. The robotic approach also makes the difficult laparoscopic pancreatectomy feasible and easier to teach.

In this chapter, we discuss indications and techniques for robotic-assisted resection of benign and malignant cystic lesions with a focus on parenchyma-preserving pancreatectomy. Given the benign nature of most cystic neoplasms, robotic resection is leading the way in technical advances that enable surgical resection of premalignant pancreatic lesions with reduced morbidity and improved patient outcomes (Table 91.1).

Indications for Robotic-assisted Resection of Cystic Neoplasms

The indications for robotic-assisted resection of cystic neoplasms (Table 91.2), including mucinous cystic neoplasms (MCN), serous cystic neoplasms, intraductal papillary mucinous neoplasm (IPMN), solid pseudopapillary neoplasm (SPN), and cystic pancreatic neuroendocrine tumors (C-PanNET), are identical to those for open and laparoscopic procedures with additional consideration given to prior history of abdominal surgery, body habitus, and tumor location. Indications for resection of asymptomatic branch-duct IPMN (BD-IPMN) include the presence of worrisome features such as the presence of mural nodules, given that nodules >5 mm have been shown to be highly predictive of invasive carcinoma and/or high-grade dysplasia. Indications for main-duct IPMN (MD-IPMN) resection include main pancreatic duct dilation >10 mm, jaundice, and mural nodules. Depending on which guidelines are followed, indications for resection of MCN include all surgically fit patients with cysts >4 cm and/or cysts causing symptoms [24–26]. Surgery for SCN is rarely indicated except when the patient has symptoms secondary to mass effect.

Overall performance status such as patient age and body mass index (BMI) should be considered when using a robotic platform. Recent data support the use of robotic pancreatic surgery for patients with BMI greater than 25 [27].

Preoperative Preparation

Prior to taking a patient to the operating room for robotic-assisted resection, it is essential to review the preoperative imaging studies including cross-sectional imaging such as high-quality pancreatic-protocol computed tomography (CT) and/or magnetic resonance imaging (MRI). Review of cyst fluid analysis (amylase, lipase, CEA, cytology) obtained from endoscopic ultrasound (EUS) should be performed if available [28]. In general, the need to remove the spleen should be determined preoperatively.

Reusable robotic instruments should be available, including EndoWrist® monopolar hook cautery, scissors, Maryland bipolar forceps, fenestrated bipolar forceps, medium-large clip applier, large SutureCut™ needle driver, and Tip-Up fenestrated grasper (Intuitive Surgical, Sunnyvale, CA, USA) [29]. If the need for intraoperative ultrasound is anticipated, it should be ready and available.

For robotic pancreatic surgery, the patient can be positioned supine with split legs and both arms untucked. Five robotic ports are placed in a linear fashion (Fig. 91.1). The robot can be docked on either side of the patient depending on the set-up in the operating room. Diagnostic laparoscopy is performed first to rule out metastasis or carcinomatosis or severe intraabdominal adhesions that would prohibit the planned robotic surgery.

Specific Surgical Considerations and Procedures

Distal Pancreatectomy +/– Splenectomy for the Resection of Cystic Neoplasms

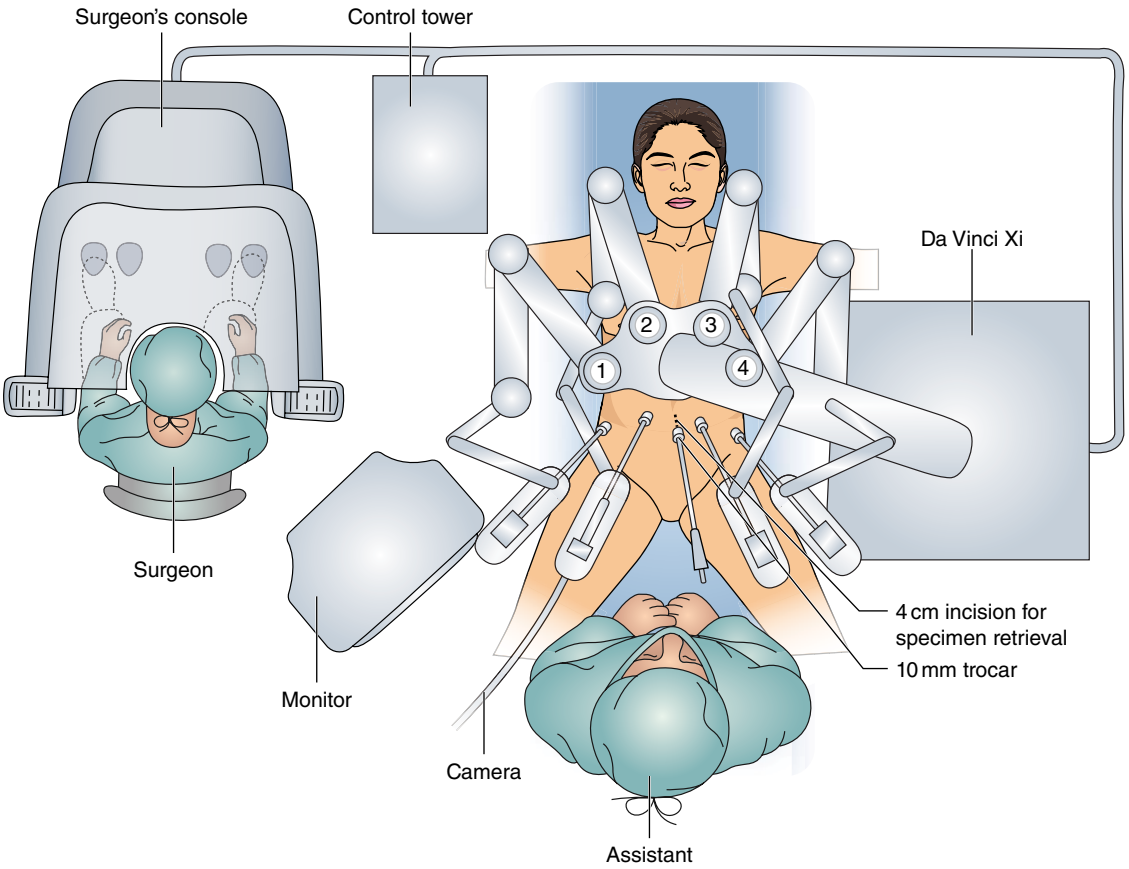
Many surgeons elevate the left side of the body with a kidney rest or similar support to facilitate intraoperative exposure of the distal pancreas and spleen hilum.

The dissection starts by dividing the gastrocolic ligament to enter the lesser sac either from the pylorus towards the gastroesophageal junction or in a clockwise approach [29,30]. The stomach is retracted anterocephalad and the splenic flexure is mobilized. The retroperitoneum is incised along the inferior aspect of the pancreas in a medial to lateral fashion to expose the superior mesenteric vein (SMV) and create a retropancreatic tunnel.

It is our routine practice to preserve the spleen for patients without malignancy whenever possible. We favor the "Kimura-first" approach to preserve the splenic vessels with conversion to the Warshaw procedure (segmental resection of the splenic vessels and preservation of the left gastroepiploic vessels and the short gastric vessels for splenic blood supply) if the splenic vessels cannot be preserved for anatomic reasons [31]. Some surgeons advocate splenic artery isolation and control prior to pancreatic division [29].

The pancreas is divided using a robotic harmonic or linear stapler, depending on the size and thickness of the gland. Dividing the pancreas first will help with dissection of the root of the splenic artery and the confluence of the splenic vein and portal vein. The splenic artery and vein can be divided with a linear vascular stapler or after suture ligation, depending on the location of the tumor. If a pancreatic duct can be identified on the cutting surface of pancreas, it should be sutured closed with a 5-0 prolene [29]. If there is high suspicion for cancer, oncologic resection should be performed to achieve negative margin and adequate lymphadenectomy.

Once the pancreas is fully mobilized off the retroperitoneum, the specimen is placed in a specimen removal bag, and removed from the body through a Pfannenstiel or enlarged assisting trocar incision. Drains are placed per surgeon preference.



Pancreaticoduodenectomy for the Resection of Cystic Neoplasms

For robotic pancreaticoduodenectomy (RPD), the first step is entering the lesser sac by dividing the gastrocolic ligament as well as the right gastric and right gastroepiploic vascular bundles, followed by dissecting the posterior stomach off the anterior pancreas. At least two approaches for proceeding with the dissection have been published [4,32,33]. One starts with dissection of the porta hepatis by identifying and transecting the cystic duct, cystic artery, and common hepatic duct and exposing the portal vein and common bile duct (CBD). The other approach begins by mobilizing the duodenum, exposing the inferior vena cava (IVC) and transecting the proximal jejunum. Next steps include portal lymphadenectomy and identification and ligation of the gastroduodenal artery (GDA). The distal stomach is divided 5 cm proximal to the pylorus using the regular Endo GIA™ stapler from the assisting trocar.

Alternatively, the proximal duodenum can be divided just distal to the pylorus if a pylorus-preserving technique is favored. The portal (PV) and superior mesenteric veins (SMV) are identified.

The pancreas is divided with the robotic harmonic and the duct is cut with cold scissors. During dissection of the uncinate process away from the superior mesenteric artery (SMA) (Fig. 91.2), the inferior pancreaticoduodenal artery is identified and divided after being clipped with Hem-o-lok® clips (Teleflex Inc., Morrisville, NC, USA). The gallbladder is dissected to be included with the pancreaticoduodenectomy specimen.

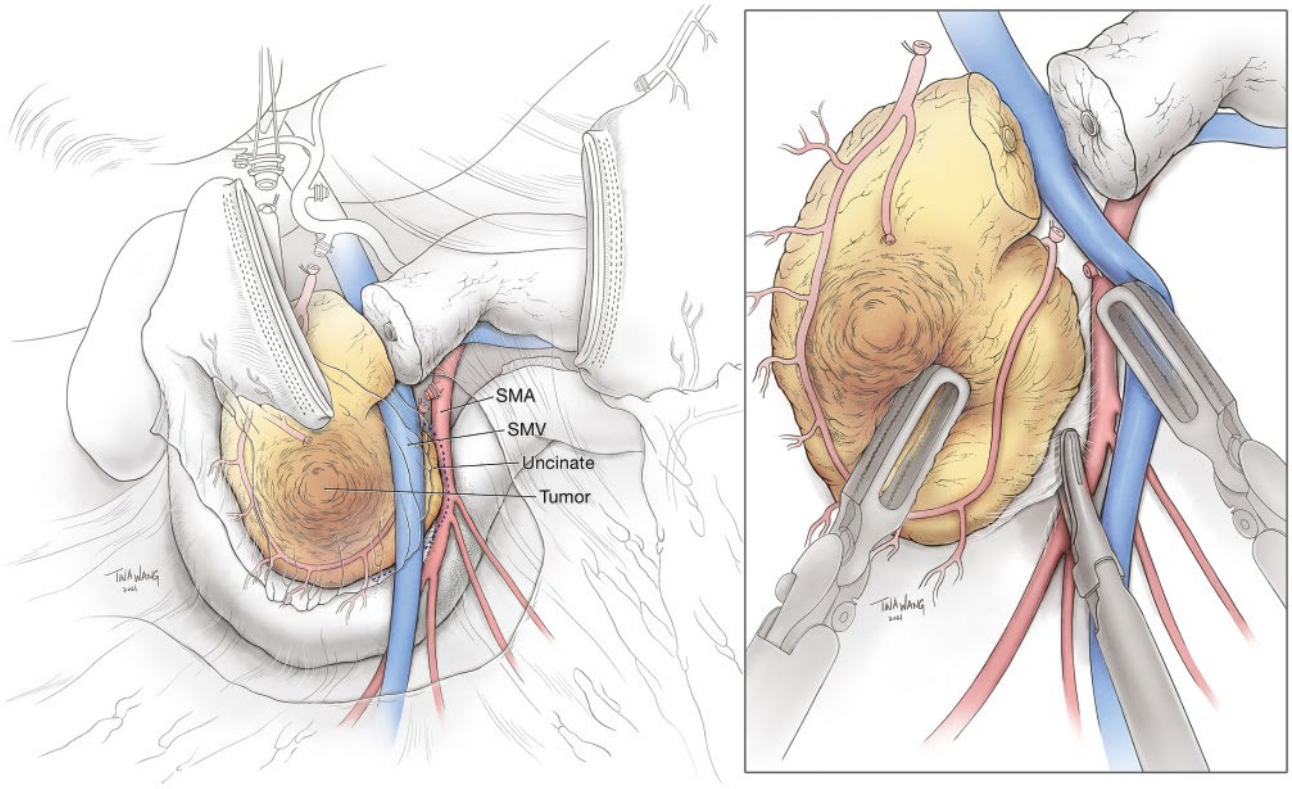

Figure 91.2 Graphic depiction of robotic separation of the uncinate from the SMA.

Robotic reconstruction proceeds conventionally in the same order as the open procedure: pancreaticojejunostomy (PJ), hepaticojejunostomy (HJ), and gastrojejunostomy (GJ). The robotic EndoWrist manipulation allows these technically challenging anastomoses to be performed with significant precision. Depending on the size and tissue quality of the pancreas, we typically perform a two-layer anastomosis for the PJ. The anterior and posterior layers are commonly sewn with either a 3-0 or 4-0 V-Loc™ running suture. The duct-to-mucosa technique is routinely performed with a 5-0 PDS interrupted suture with placement of a pediatric feeding tube as an internal PJ stent. Approximately 5–10 cm distal to the PJ, the HJ is created in an end-to-side fashion with two 4-0 V-Loc running sutures. An antecolic side-to-side anastomosis is commonly chosen for the GJ. This anastomosis can be created with a regular Endo GIA stapler from the assisting trocar.

We close the enterotomy with a 3-0 V-Loc running suture. The falciform ligament is routinely used to wrap the GDA stump so we can separate the GDA stump away from the surrounding PJ and HJ anastomoses. Drains are placed around anastomoses and the specimen is removed through the enlarged assisting trocar incision.

Cyst Resection/Enucleation

Parenchyma-preserving pancreatectomy including enucleation is not recommended for MD-IPMN, cyst <2 mm from the main pancreatic duct, multifocal cystic lesions, and lesions >4-6 cm in size given their higher rate of associated malignancy [34]. Briefly, indications for excision most commonly include isolated C-PanNET, BD-IPMN >2 mm distance from the main duct, and MCN lesions in the head and body that are less than 4 cm in diameter [34,35].

Exposure for lesions in the head [36] begins by opening the gastrocolic ligament to explore the head and neck of the pancreas whereas direct entry into the lesser sac is the preferred approach for lesions in the body/tail. Given the focused nature of enucleation, intraoperative ultrasound is highly recommended in order to confidently identify the lesion, rule out the presence of intramural nodules, assess its proximity to the main pancreatic duct, and minimize parenchymal dissection. It is our routine practice to check intraoperative frozen section pathology to confirm that the resected lesion is benign in nature. If there is cytologic concern for malignancy, we convert the parenchyma-preserving surgery to a formal oncologic resection [34].

Once the tumor has been circumferentially dissected and removed, the resection bed is examined to achieve hemostasis. The use of indocyanine green fluorescence to visualize the biliary anatomy is critical to avoid unnecessary injury to the bile duct. If the main pancreatic duct is injured, it can be repaired with 6-0 PDS sutures with the placement of an internal stent. Some studies support the practice of closing the pancreatic parenchyma with absorbable suture after the enucleation has been completed, citing evidence that doing so may reduce the incidence of postoperative pancreatic fistula [34]. Many surgeons routinely leave drains to assess for postoperative pancreatic fistula. Recovery time is shorter, with similar morbidity and mortality for cysts that are enucleated with robotic assistance compared to open enucleation.

Central Pancreatectomy with Pancreaticogastrostomy or Pancreaticojejunostomy

Central pancreatectomy is a conservative approach for surgical resection of benign, premalignant and low malignant potential tumors of the pancreatic neck and proximal pancreatic body. First reported in the literature by Dr Oskar Ehrhardt of Prussia in 1907 and Dr Finney in the United States in 1910, the technique of central pancreatectomy and stump ligation/reconstruction has continued to evolve over the last century [37]. Pancreatic fistula was a frequent early complication as surgeons navigated the best way to reconstruct both the proximal and distal pancreatic stumps. Currently, lesions recommended for central pancreatectomy are <3 cm in size and located >5 cm from the tip of the pancreatic tail.

Exposure of the pancreas proceeds as previously described. Once the location of transection is identified, the pancreatic neck is transected proximally using a robotic harmonic or a linear stapler, depending on the size and thickness of the gland, followed by the distal transection encompassing the lesion. Use of intraoperative ultrasound is essential to confirm that the lesion of interest is bounded by the two transection planes. Once the specimen is resected, intraoperative frozen margin evaluation is used to evaluate the margins and ensure lack of tumor tissue.

Reconstruction options depend on surgeon's preference and how difficult it is to mobilize the distal pancreas. Pancreaticogastrostomy is possible and avoids the need for Roux limb creation whereas pancreaticojejunostomy is fashioned in the routine Roux-en-Y manner. Comparative studies of PG versus PJ after central pancreatectomy found that patients undergoing PG had fewer postoperative intraabdominal fluid collections, less delayed gastric emptying, fewer pancreatic fistulae, fewer readmissions and postoperative complications compared to those undergoing PJ [38,39]. However, a Cochrane review of 10 randomized studies found no difference between PG and PJ although the quality of available evidence was low [40].

Robotic-assisted central pancreatectomy has been reported since 2010 [41,42], along with a recent description of an end-to-end pancreatic anastomosis technique for benign and low malignant potential neoplasms [43].

Total Pancreatectomy

Total pancreatectomy is an option for patients with diffuse IPMN and multifocal PanNET [44]. Despite its technical and postoperative challenges such as brittle diabetes and absent exocrine function, total pancreatectomy can be considered in selected patients. Using the current Xi robotic platform, the entire gland can be dissected and mobilized for excision.

Surgical Outcomes

Estimated blood loss (EBL), conversion to open, operative time, postoperative mortality, postoperative pancreatic fistula (POPF), and Clavien-Dindo grade 3–5 complications (such as sepsis, anastomotic leak, delayed gastric emptying [DGE], fascial dehiscence, myocardial infarction, pleural effusion, pulmonary embolism, respiratory failure and small bowel obstruction) as well as length of stay (LOS) are the most commonly tracked general outcomes when comparing open pancreatic resection to robotic surgical resection [7,11]. For robotic pancreatic surgery specifically, EBL, LOS, splenic preservation in distal pancreatectomy, and conversion to an open procedure have been shown to be statistically lower for robotic versus laparoscopic pancreatic resection [7,21]. Other outcomes such as wound infection, DGE, sepsis, POPF, and 30- and 90-day mortality were all statistically equivalent while financial cost and operative time were increased using the robotic platform compared to traditional laparoscopy [7,21].

Though less relevant to cystic tumor resection, oncologic-specific outcomes have been found to be equivalent in both laparoscopic and robotic pancreatic tumor resection when compared to open resection [45,46].

Widespread Adoption

In a recently published worldwide survey on the opinions and use of minimally invasive pancreatic resection, 435 surgeons from 50 countries shared their perspectives on the utility of minimally invasive and robotic pancreatic procedures [47]. Ninety percent of respondents

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

felt that minimally invasive pancreatic surgery was beneficial for patients, with 81% of respondents stating that they felt that robotic pancreatic resection was equivalent or superior to laparoscopic resection. Of the surgeons who felt that robot-assisted surgery was superior, the improved dexterity, superior ergonomics, and improved visibility were the top three reasons cited. Among surgeons surveyed, lack of training in minimally invasive and robotic techniques was cited most frequently as the reason for not routinely performing these procedures.

To address the need to train the next generation of surgical oncologists and hepatobiliary surgeons in robotic techniques, surgeon researchers from the University of Pittsburgh Medical Center studied and implemented a robotic surgery pilot curriculum. Results showed that time spent on the curriculum was associated with increased percent mastery as measured by virtual reality performance. However, lack of protected time and limited access to the robotic simulator were two of the primary reasons cited by trainees who were unable to fully participate in the curriculum as envisaged [48].

Conclusion

Robotic-assisted minimally invasive pancreatic surgery has been shown to be safe and effective with equivalent or improved outcomes compared to laparoscopic and open pancreatic surgery. Specific to resection of pancreatic cystic neoplasms, which are most commonly benign, a robotics approach is now favored at some institutions given its increased degrees of rotational freedom, improved ergonomics, and better visualization. Global use, proficiency, and safety of robotic-assisted pancreatic surgery have significantly evolved over the last decade and will continue to advance. Improved patient outcomes and the technical advantages of robotic-assisted surgery over more traditional approaches set it apart as the future of pancreatic surgery for selected indications.

Duodenum-preserving Pancreatic Head Resection for Cystic Neoplasms of the Pancreatic Head: Indications and Limitations

Hans G. Beger[1] *and Bertram Poch*[2]

[1] *University of Ulm, Germany*
[2] *Center for Oncologic, Endocrine and Minimally Invasive Surgery, Donau-Klinikum, Neu-Ulm, Germany*

Introduction

Standard surgical treatments for benign cystic neoplasm of the pancreas are currently pancreatoduodenectomy (PD) for tumors of the pancreatic head and a left-sided pancreatic resection, either spleen-preserving or with splenectomy, for tumors in the body and tail. Many of the cystic neoplasms are benign and small (tumor size <3 cm) at the time of diagnosis. The question arises as to why a surgical treatment with radical resection of the tumor-bearing pancreas, associated with tissue loss of the duodenum, pancreatic head, extrahepatic biliary ducts and gastric antrum, is applied for a benign lesion. Parenchyma-sparing, local resection procedures for pancreatic tumors are recommended. They have the potential of low procedure-related postoperative morbidity and preservation of exocrine and endocrine pancreatic functions [1,2].

Classic Pancreatoduodenectomy or Local Extirpation for Cystic Neoplasms of the Pancreatic Head?

Currently, the standard treatment for a benign cystic neoplasm in the pancreatic head is the Kausch–Whipple resection or pylorus-preserving PD. PD is a multiorgan resection associated with considerable loss of functional pancreatic and extrapancreatic tissue. It is associated with the risk for severe postoperative complications, including pancreatic fistula, disruption of anastomosis, surgical side abscess, intraabdominal hemorrhage and delayed gastric emptying, requiring reoperation and/or reintervention in 5–12% of cases [3,4]. Hospital mortality after PD in high-volume institutions ranges betweeen 3% and 5%. However, 90-day mortality rates as high as 4–8% have been reported [4–6]. Postoperatively, new diabetes mellitus develops in 12–20% of patients after surgical resection of a benign or premalignant pancreatic tumor [7–11]. In total, 30–40% of preoperative diabetic patients display postoperatively an escalation to insulin-dependent diabetes [11]. Following PD, exocrine pancreatic functions are significantly reduced in 30–50% of patients [12]. The PD-inherent duodenectomy effects long-lasting dysfunction of secretion of gastrointestinal hormones and gastrointestinal motility disorders [13–16] (Table 92.1).

Duodenum-preserving total pancreatic head resection for benign pancreatic head tumors is associated with low postoperative surgery-related morbidity and a very low hospital mortality [18]. A metaanalysis published in 2015 on functional changes before and after DPPHR and PD revealed that exocrine and endocrine pancreatic functions following DPPHR were almost unchanged, in contrast to PD [8]. Despite the resection of pancreatic head tissue, total duodenum-preserving pancreatic head resection maintains endocrine functions, as reflected by HBA1c levels, glucose tolerance testing and the frequency of postoperative new-onset diabetes mellitus [8]. DPPHR preserves exocrine functions, whereas after PD there is often a significant decrease, requiring enzyme supplementation. The probability of developing endocrine and exocrine pancreatic insufficiency one year and five years following PD was found to be 32% and 85%, respectively [19].

[b] PD for benign tumors only.

Rationale for Parenchyma-sparing Pancreatic Head Resection

The rationale for local resection of benign tumor in the pancreatic head includes: (i) preserving the duodenum, distal biliary ducts, and gallbladder as well as gastric antrum and pylorus; (ii) maintenance of the functional integrity of the duodenum regarding coordination of digestive, metabolic, and motility functions of the pancreas, liver, and stomach respectively; (iii) conserving a maximum of the pancreatic tissue; (iiii) protecting the patient against metabolic and nutritional, long-term GI tract disorders of glucose metabolism and disturbances of carbohydrate, fat, and protein digestion.

The goals of limited, local pancreatic head resection are: (i) application of a procedure with low risk for surgery-related severe complications and hospital mortality, superior to the standard surgical procedure; (ii) maintenance of patient quality of life; (iii) prevention of fear of tumor growth and of suffering from pancreatic cancer.

Duodenum-preserving Total Pancreatic Head Resection with or without Segmental Resection of the Peripapillary Duodenum and the Intrapancreatic Common Bile Duct

Tumor size and location, radiomorphologic type, and histopathology of the neoplasm determine whether a total or partial pancreatic head resection should be undertaken (Table 92.2).The surgical technique of DPPHR is almost identical to the standard PD procedure except for dissection of the pancreatic head along the duodenal wall and conservation of the intrapancreatic common bile duct (CBD), and in some instances resection of a 4 cm segment of the peripapillary duodenum. To preserve the duodenum and intrapancreatic CBD, a total pancreatic head resection (DPPHR-T) entails complete resection of the pancreatic head, including the uncinate process (Fig. 92.1).

Duodenum-preserving total pancreatic head resection with segment resection of the peripapillary duodenum comprises total pancreatic head extirpation and resection of the segment of the peripapillary duodenum and the intrapancreatic CBD, while preserving the pancreatic neck (Fig. 92.2). Three anastomoses need to be performed to ensure postoperative GI integrity. An excluded jejunal loop or the stomach is used for anastomosis of the left pancreas. Partial pancreatic head resection is performed by extirpating the tumor-bearing tissue from the pancreatic head or resecting of the uncinate process (Fig. 92.3). A duodenum-preserving total pancreatic head resection with preservation of the peripapillary duodenum and intrapancreatic CBD is associated with a higher frequency of local complications in the area of the peripapillary duodenum and intrapancreatic CBD [18].

Duodenum-preserving total or subtotal pancreatic head resection has been applied in two-thirds of patients with a monocentric cystic neoplasm of the head of pancreas (Table 92.3). Most total head resections have been

performed for an intraductal papillary mucinous neoplasm (IPMN), followed by serous cystadenoma (SCA); in one-third of cases a partial, subtotal head resection was performed, whereas in two-thirds of cases a total, parenchyma-sparing head resection was executed. Approximately 10% of the cystic neoplasms resected by local head resection have been reported to contain high-grade dysplasia. The procedure-related morbidity included severe complications (Clavien–Dindo >3); POPF B+C; reoperation; rehospitalization; 90-day mortality. After a mean follow-up time of 62 months, recurrence was observed in 2.9% of cases (Table 92.4).

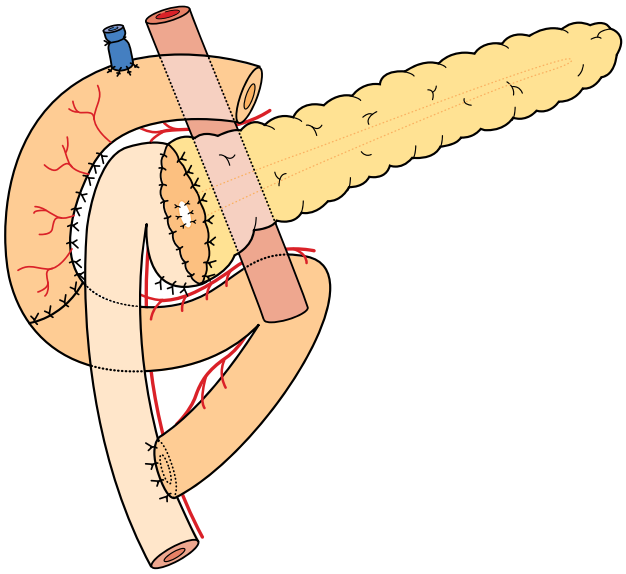

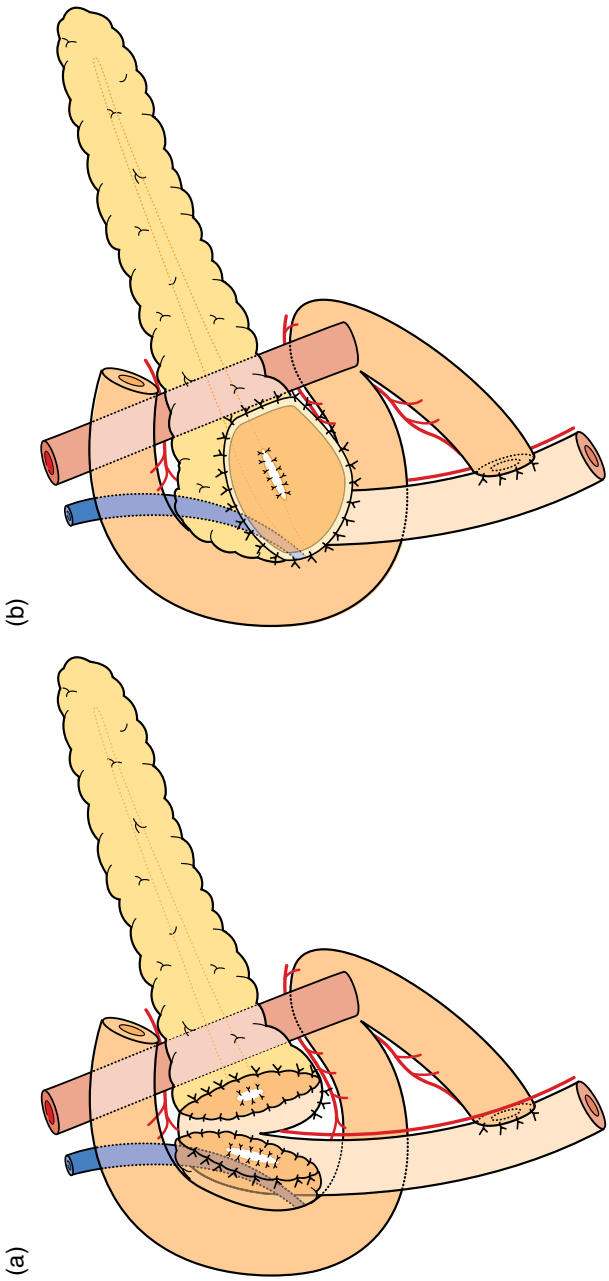

Figure 92.2 Duodenum-preserving total pancreatic head resection including resection of peripapillary duodenum and CBD.

Conclusion

For surgical treatment of benign and low-risk cystic neoplasms of the pancreatic head, a local, parenchyma-sparing head resection offers major benefits to the patient by maintaining quality of life. The advantages of duodenum-preserving total or partial pancreatic head resection compared to PD are a low surgery-related early postoperative morbidity and a very low hospital mortality. Local pancreatic head resections are

associated with almost complete conservation of endocrine and exocrine pancreatic functions. The risk of recurrence after local head resection of cystic neoplasms, including high-grade dysplasia, is very low provided frozen section investigation is used to exclude an advanced cancer.

Pancreatic Middle Segment Resection of Cystic Neoplasms: Indications and Limitations

Calogero Iacono and Mario De Bellis

Department of Surgery, Unit of Hepato-Pancreato-Biliary Surgery, University of Verona Medical School, University Hospital "G.B. Rossi", Verona, Italy

Introduction

Pancreatic middle segment resection (PMSR), also known as the Dagradi–Serio–Iacono operation, central pancreatectomy, middle pancreatectomy, medial pancreatectomy, intermediate pancreatectomy, and limited conservative pancreatectomy, is a parenchyma-sparing operation that is indicated for the removal of benign or low-grade malignant tumor of the isthmus and proximal part of the pancreas body (Fig. 93.1) [1]. Compared to pancreaticoduodenectomy (PD) and distal pancreatectomy (DP), PMSR is associated with a lower risk of postoperative pancreatic exocrine and endocrine insufficiency. In addition, this type of pancreatic resection spares the spleen, preventing infective and thromboembolic complications, and also spares the upper digestive and biliary tract, which is not possible in PD, avoiding digestive disorders.

The first PMSR was performed in 1982 by Dagradi and Serio resecting a neuroendocrine tumor (insulinoma) located in the neck of the pancreas and was reported few years later in the Enciclopedia Medica Italiana [2]. Subsequently, Iacono validated PMSR using functional endocrine and exocrine tests and popularized it all over the world [3]. These findings were included in several international reports demonstrating that there is almost no postoperative impairment of endocrine and exocrine functions when appropriate indications and technique are respected [2–4]. In recent decades, several authors have reported clinical series on patients who underwent PMSR, demonstrating that this operation has become a standardized technique commonly applied in the surgical treatment of pancreatic diseases [3,4]. Currently, PMSR is performed worldwide either by traditional open surgery [2–9] or by minimally invasive approaches [2,4,10–12].

Indications

Pancreatic middle segment resection can be performed for low-grade malignant or benign lesions between 2 and 5 cm in size, where the close relationship between the lesion and the main pancreatic duct (MPD) prevents a simple enucleation because of the risk of duct injury and consequently high-output and prolonged pancreatic fistula (PF). The main indication concerns cystic neoplasms, but PMSR can also be performed for neuroendocrine tumors or other nonneoplastic lesions.

The indications are summarized as follows:

- neoplastic cystic lesions as symptomatic serous cystadenoma (see Fig. 93.1), mucinous cystadenoma, solid cystic pseudopapillary tumors, selected cases of intraductal papillary mucinous neoplasm (IPMN)
- nonneoplastic cysts such as simple lymphoepithelial or hydatid cysts
- small neuroendocrine tumors (especially functioning)
- focal chronic pancreatitis with isolated short stenosis of the MPD
- solitary metastases located at the pancreatic neck (i.e., from kidney cancer).

Contraindications

The contraindications are as follows.

- A short distal remnant pancreas stump (less than 5 cm in length).
- Atrophy of the body–tail of the pancreas.
- Diagnosis of malignant tumors (i.e., pancreatic ductal adenocarcinoma).

- Evidence of tumors originating from nearby organs and infiltrating the pancreas.
- Diffuse or focal chronic pancreatitis not involving the central part of the gland.
- The presence of vascular variant type III according to Mellière and Moullé, where the arterial supply for the body–tail of the pancreas is maintained exclusively from the transverse pancreatic artery (left branch of the dorsal pancreatic artery).

Technique

The PMSR consists of a resection phase that ends with the resection of the central pancreatic segment (isthmus and/or proximal body) (Fig. 93.1d) and a subsequent reconstructive phase which involves suturing the MPD of the cephalic stump and performing the digestive anastomosis with the distal stump (Fig. 93.1e) [1,3,13,14].

Resection phase

Open PMSR requires a midline incision. Access to the lesser sac is achieved by dividing the plane of fusion between the omentum and the transverse colon (the authors' preferred procedure) or through the section of the gastrocolic ligament. When the pancreatic gland is widely exposed, the surgeon can proceed with the pancreatic ultrasonography to better identify the extent and anatomic relationships of the lesion and/or to guide fine needle biopsy in cases of uncertain preoperative diagnosis.

After the proximal section of the pancreatic isthmus, the splenomesenteric axis, and the splenic vein and artery are dissected free from the posterior surface of the gland. The surgeon should be aware that the presence of a large dorsal pancreatic artery raises a high index of suspicion that the left pancreatic blood supply is exclusively maintained by the transverse pancreatic artery. This vascular variation is, as previously mentioned, a clear contraindication to PMSR. In fact, section of the artery would lead to necrosis of the pancreatic body–tail. Occasionally, it is necessary to isolate and mobilize the common hepatic artery to divide those branches originating from it (i.e., dorsal pancreatic artery) that supply the central pancreas. The extent of PMSR is limited on the right by the gastroduodenal artery and on the left by at least 5 cm of normal pancreatic remnant.

After stay sutures are placed in the superior and inferior pancreatic margins to indicate the proximal and distal limits of division, the pancreatic cephalic end is transected using either a scalpel or a stapler. For the distal side, the resection should be performed with a scalpel in order to avoid damage to the splenic artery or vein. The resected specimen is then sent to the pathologist to verify that the resection margins are adequate and to confirm the diagnosis by frozen sections. In case of intraoperative diagnosis of malignant tumor, the operation has to switch to PD or DP (splenopancreatectomy) with lymphadenectomy. Hemostasis of the two raw surfaces is achieved with interrupted nonabsorbable stiches, and the integrity of the main pancreatic duct on the distal stump is preserved by the insertion of a small catheter. In the presence of IPMN, a pancreatoscopy can be performed, just after resection, through the MPD in both stumps to rule out other ductal lesions.

Reconstructive phase

The MPD of the cephalic stump, when not stapled, is sutured selectively with figure-of-eight nonabsorbable stitches; the pancreatic stump is sutured along the entire length with a row of interrupted and overlapping mattress-type stitches.

The digestive anastomosis of the distal stump can be performed using several techniques commonly applied in PD. Roux-en-Y pancreaticojejunostomy can be conducted in different ways: end to end (simple or telescopic invagination), end to side, duct to mucosa, and side to side (Puestow procedure or Partington–Rochelle technique if the duct of Wirsung is dilated as in chronic pancreatitis). Some authors also perform an anastomosis of the cephalic stump using the same jejunal loop (double pancreaticojejunostomy). Pancreaticogastrostomy is usually performed by implantation of the open end of the pancreas directly into the gastric pouch through a 2–3 cm opening in the posterior surface.

Another type of reconstruction is the end-to-end anastomosis of the MPD and parenchyma, with or without stent placement for internal or external pancreatic juice drainage [15]. In the past, this reconstruction was used to repair traumatic pancreatic neck transections with minimal loss of parenchyma. Notably, the MPD of most patients who undergo PMSR is too thin (not dilatated) to confidently perform duct-to-duct anastomosis. The posterior and anterior parts of the anastomosis were closed with stitches that were tied one after another. To avoid any damage to the duct of Wirsung, a small catheter was introduced before the stitches were inserted and was removed just prior to the stitches being tied. Currently, we prefer to perform a duct-to-mucosa leaving a plastic transanastomotic catheter (Fig. 93.1e).

The operation concludes with the end-to-side jejunojejunostomy with a double layer of absorbable stitches, approximately 50 cm distal to the pancreatic anastomosis. Lastly, two soft drains are placed; one close to the proximal pancreatic stump and the other close to the digestive anastomosis.

Minimally invasive approach

In the laparoscopic procedure, the patient is placed in supine or reverse Trendelenburg position, with the surgeon standing between the patient's legs. Four trocars are placed under direct scope vision [12]. In the robotic-assisted technique, patient position is similar but the surgeon operates from the console. Four ports are placed for the robotic arms and an additional port is inserted in the left lower quadrant and used for assistant-surgeon and Endo GIA^{TM} application [16]. The minimally invasive approach follows the same steps as the open technique. After completing the dissection phase, the resected specimen is placed in an entrapment bag and delivered through the extension of the umbilical incision.

Results

Recent advances in diagnostic imaging have resulted in an increased incidence of incidental benign, low-grade, small-sized tumors of the pancreas, some of which require surgical resection. Especially in young and middle-aged patients with long life expectancy, PMSR is an excellent alternative to conventional pancreatectomies as it preserves healthy functional pancreatic parenchyma and accordingly pancreatic endocrine and exocrine function, improving quality of life after surgery. Nevertheless, PMSR is still performed less frequently than PD or DP, probably because the operation is technically demanding and requires specific surgical experience. Nowadays PMSR is mainly performed in specialized centers by either open or minimally invasive approach.

In the last decade, minimally invasive pancreatic surgery has undergone fast development even if most of the cases are still performed by an open approach. In series reporting at least 50 patients who underwent PMSR by the open approach [9,17–22], the severe complication and clinically relevant pancreatic fistula (PF) rates were 12–36% and 8–44% respectively, while the incidences of endocrine and exocrine insufficiencies were 0–15% and 0–10%, respectively (Table 93.1). The

type of surgery does not influence morbidity and mortality, nor the long-term outcomes. However, compared to open PMSR, laparoscopic PMSR is associated with lower estimated blood loss, reduced postoperative pain, faster recovery, and better quality of life [23] while robotic PMSR seems to be associated also with reduced operative time and clinical PF rates, according to the largest randomized controlled trial published so far [20]. An international consensus on robotic pancreatic surgery states that robotic PMSR is feasible and safe, but there is still little evidence to support the better short-term outcomes of robotic PMSR versus open resection [24]. PMSR outcomes by laparoscopic [25–28] and robotic [20,29,30] approach are summarized in Table 93.2. Studies comparing outcomes of laparoscopic versus robotic approach are lacking.

Robotic technology allows wristed articulation of the surgical instruments, three-dimensional high-definition visualization with variable magnification, and computer-aided dexterity to enhance the precision of placing fine sutures in the pancreatic duct. These benefits may help the surgeon to perform more complex laparoscopic procedures, especially for pancreatic anastomosis.

There are three types of reconstruction for distal pancreatic stump: pancreatogastrostomy (PG), pancreaticojejunostomy (PJ), and end-to-end pancreatic anastomosis. PJ is the most commonly performed reconstruction despite involving a Roux-en-Y jejunal anastomosis [4]. In contrast, PG does not require bowel mobilization and division and thereby avoids any increase in operative time, the interruption of intestinal continuity and potential leaks. PG is easier and faster for just one anastomosis (slightly preferred in minimally invasive approaches [31]) but is associated with delayed oral feeding, prolonged hospital stay, and long-term impairment of exocrine pancreatic function [23]. Lastly, end-to-end pancreatic anastomosis has the advantage of maintaining the integrity of the gastrointestinal tract and reducing operative time, but involves complex suturing of the Wirsung duct stumps, which can be very small or of different caliber, and extensive mobilization of the pancreatic stumps which need to be moved closer [15].

The best type of pancreatic anastomosis is still debated; the authors recommend using the procedure with which the surgeon is most confident. Thorough patient selection is essential for the benefits of PMSR to outweigh the possible complications [4].

Although PF is the most frequent complication in PMSR, only a minority of patients show a clinically relevant PF according to the International Study Group on PF (ISGPF) classification. This is due to the fact that there are two pancreatic stumps, and the anastomosis is usually performed on a soft pancreas with a nondilated main pancreatic duct. Interestingly, according to the published reviews [4,31], less than 5% of patients undergo reoperation for severe complications (PF, bleeding, intraabdominal collections, pancreatitis of the distal stump, bowel obstruction) and the mortality rate is below 1%. These results suggest that PMSR is a safe and feasible procedure. PMSR compared to DP showed no significant differences in reexploration, mortality, and clinically relevant PF, whereas PMSR was associated with lower intraoperative blood loss, higher morbidity, longer operating times, and longer hospital stay.

Regarding long-term outcomes, PMSR is an excellent alternative to DP as it preserves pancreatic endocrine and exocrine function to avoid new onset of diabetes mellitus and pancreatic exocrine dysfunctions in almost all patients in the long term. In fact, following left-sided pancreatic resection, exocrine dysfunction was observed in 12–18% of patients while new-onset diabetes or worsening preexisting diabetes was observed in 14–39% of patients [32,33]. PMSR, instead, shows significantly lower rates of overall endocrine and exocrine insufficiency, at 0–15% and 0–10%, respectively (see Table 93.1).

By following the right indications and careful selection of patients, PMSR can be considered the treatment of choice and not just an alternative to DP.

Conclusion

Pancreatic middle segment resection is a parenchyma-sparing surgery that preserves the functional tissue of the pancreatic body–tail where there are numerous islet cells releasing hormones and acinar cells producing digestive enzymes. Therefore, pancreatic exocrine and endocrine functions are usually maintained. Furthermore, PMSR avoids the infective and thrombotic complications commonly associated with splenectomy and could achieve a better quality of life after surgery, especially in young patients with long life expectancy. Despite the high risk of PF, probably due to the two pancreatic stumps, PMSR has demonstrated low rates of clinically relevant PF and reoperation. In addition, the mortality rate is almost nil. Hence, PMSR is a feasible and safe technique (either open or minimally invasive) that should be included in the armamentarium of the modern pancreatic surgeon. The laparoscopic approach appears to reduce hospital stay by promoting early recovery while a robotic-assisted technique may stimulate the surgeon to perform complex procedures more easily, effectively, and precisely. Nevertheless, careful case selection, accurate pre- and intraoperative evaluation of the lesion, and experience in pancreatic surgery are recommended to achieve optimal results.

Tumor Enucleation for Cystic Neoplasms of the Pancreas: Indications and Limitations

Rachel C. Kim[1], *C. Max Schmidt*[1], *and Henry A. Pitt*[2]

[1] *Indiana University School of Medicine, Indianapolis, IN, USA*
[2] *Rutgers Cancer Institute of New Jersey, Robert Wood Johnson Medical School, New Brunswick, NJ, USA*

Introduction

Cystic neoplasms of the pancreas are increasingly diagnosed due to improvements in modern imaging modalities. Nearly 3% of all patients undergoing abdominal computed tomography (CT) and up to 50% of those undergoing abdominal magnetic resonance imaging (MRI) will have an incidentally detected pancreatic cystic lesion [1,2]. This number varies significantly according to the size of the cyst and the threshold of radiologists to report them. A recent prospective study found the prevalence of incidental pancreatic cysts >1 cm in size to be 6% in the studied population, and cysts >5 mm in size to be 37% [3]. While many cysts are benign, most carry some risk of malignancy, and all have the potential to cause symptoms.

Diagnosis is often unclear despite multiple strategies including CT, endoscopic ultrasound (EUS), magnetic resonance cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP), and fine needle aspiration (FNA) with cytology and cyst fluid biochemical and DNA analysis. A definitive diagnosis may be difficult without surgical resection. Treatment of these lesions must therefore balance the diagnostic and therapeutic benefit against the significant morbidity and potential mortality of surgical resection. If patients require surgical treatment, techniques associated with lower morbidity must be considered. In select cases, cyst enucleation is an effective option with lower morbidity and mortality than pancreatic resection [4–6].

Indications

A major challenge of pancreatic cyst enucleation is appropriate patient selection. Careful characterization of the cyst is necessary to determine if an indication exists for enucleation. Selection can be done with a thorough preoperative evaluation. The first step is cross-sectional imaging (CT or MRI-MRCP with thin slices). Additional diagnostic tests may help in diagnosis and oncologic risk stratification, including EUS with FNA for cyst fluid cytology and biochemical/DNA analysis, as well as ^{68}Ga-DOTA-PET/CT for pancreatic neuroendocrine tumors (PNETs). Figure 94.1 demonstrates MRCP of a branch-duct intraductal papillary mucinous neoplasm (BD-IPMN) eligible for cyst enucleation. Radiographic and biologic work-up must take place in order to rule out malignancy, vascular involvement, and metastases, as these are all contraindications to enucleation [7].

Many lesions amenable to resection also may be eligible for enucleation. Patients who are symptomatic or have signs of malignant/premalignant pancreatic lesions generally should undergo surgical resection. Symptomatic pancreatic cysts should be resected, not only to alleviate symptoms but also due to the increased risk of malignancy associated with symptomatic lesions [8]. If evidence strongly suggests the lesion is malignant, an oncologic resection should be performed without consideration of enucleation. Findings consistent with malignancy include lymphadenopathy, mural nodules, and solid components [7]. Lesions with uncertain diagnosis or lesions that are premalignant may be appropriate

for cyst enucleation. When no oncologic need exists for traditional pancreatic resection, enucleation can avoid unnecessary sacrifice of pancreatic parenchyma, minimizing the risk of pancreatic exocrine and endocrine insufficiency [5,6].

Although pancreatic neuroendocrine tumors (PNET) are the most common lesion removed via cyst enucleation, many other cyst types are suitable for this method of resection [9]. These include, but are not limited to, mucinous cystic neoplasms (MCN), BD-IPMN [10], serous cystic neoplasms (SCN), and solid pseudopapillary neoplasms (SPN) [6,11]. Table 94.1 lists criteria for enucleation based on specific pathology. Cyst enucleation is considered the procedure of choice for most functional PNETs with a low risk for malignancy as long as technically feasible [7,9]. Nonfunctional PNETs should be enucleated if less than 2 cm and N0M0.

Table 94.1 Indications for pancreatic cyst enucleation.

Pathology	Criteria
Nonfunctional PNET	<2 cm, N0M0
Functional PNET	If technically feasible with low risk for malignancy
MCN	If likely benign; <4 cm; no mural nodules
BD-IPMN	Rapidly increasing size; symptomatic
SCN	Only if symptomatic
SPN	If technically feasible and no evidence of malignancy

BD-IPMN, branch-duct intraductal papillary mucinous neoplasm; MCN, mucinous cystic neoplasm; PNET, pancreatice neuroendocrine tumor; SCN, serous cystic neoplasm; SPN, solid pseudopapillary neoplasm.

The Sendai and Fukuoka guidelines address indications for surgical resection of MCN and BD-IPMN [8]. MCN should be removed and may be enucleated if they appear benign on imaging, are less than 4 cm, and do not contain mural nodules. The indications for resection of BD-IPMN are more controversial. These lesions are often observed, but may require resection if symptomatic or high-risk features exist such as rapidly increasing size, high-grade atypia, associated main duct dilation (early main duct involved IPMN), and mural nodules [8]. Symptomatic BD-IPMNs or those that are increasing in size but without other high-risk features may be considered for enucleation if technically feasible. If features suspicious for malignancy are present, a formal resection should be performed.

Because SCNs carry a very low risk of malignancy, they are generally only resected if the diagnosis is in doubt or if symptomatic. However, if they are allowed to grow, enucleation may no longer be technically possible. Thus, the decision for surgical management should be made on an individual basis.

If surgical resection is indicated, assessment of patient fitness must be undertaken. This assessment includes evaluation of comorbid conditions, nutritional status, and psychosocial health. Patients should be assessed for fitness for both enucleation and formal resection since the operation may convert to resection based on intraoperative findings. Fitness is not only an important factor in determining patient tolerance of the procedure, but also in determining life expectancy. Patients with limited life expectancy may be more likely to die of alternate diagnoses than cyst-related causes. In this case, a surgical procedure would not extend their life and would put them at undue risk of surgical complications.

Contraindications

Table 94.2 lists the major contraindications to pancreatic cyst enucleation. Patients with known or suspected malignancy should not undergo enucleation and instead should have an oncologic resection with negative margins and lymph node dissection [9,12]. Diagnosis of malignancy is based on symptoms, radiographic images, cytopathology, and DNA profile. Despite these multiple diagnostic tools, a definitive diagnosis of malignancy is often difficult to achieve preoperatively. In those cases, consultation with experts and the patient is necessary to determine the best course of action.

Table 94.2 Contraindications to pancreatic cyst enucleation.

Suspected malignancy
Pancreatic duct involvement/close proximity
Location in tail
Large size
Multifocality
Poor patient fitness

The surgeon may elect to begin the operation as a parenchyma-sparing enucleation until they encounter evidence of malignancy intraoperatively. Malignant cysts can be difficult to dissect due to adherence to surrounding parenchyma.

Whether or not the surgeon suspects malignancy, intraoperative frozen section pathology confirmation of invasive cancer necessitates conversion to formal pancreatic resection.

The lesion's proximity to the main pancreatic duct is an important technical consideration for enucleation. If the cyst involves the main duct, enucleation cannot be achieved without transection of the duct and therefore is contraindicated [12]. Additionally, cysts involving the main duct, specifically main duct IPMN (MD-IPMN), are at a greater risk of conversion to invasive cancer and thus require formal resection [8]. Enucleation also may be contraindicated based on the cyst's close proximity to the main duct. Risk of injury and subsequent pancreatic fistula is greatly increased (70%) when the cyst is within 2 mm of the duct [13,14]. Distance of 2–3 mm between the cyst and the main pancreatic duct is safe for cyst enucleation and can be determined with preoperative imaging such as MRCP and EUS [15,16]. During surgery, this safe distance is confirmed with intraoperative ultrasound (IOU).

Location of the cyst within the pancreas is also important when considering enucleation. If located in the tail of the pancreas, enucleation does not save much parenchyma compared to distal pancreatectomy and thus would offer no benefit.

The mean size of enucleated pancreatic cysts is 2.4 cm [9]. This relatively small size is due to the relationship between larger size and higher likelihood of malignancy [8]. The size at which enucleation may be safely performed is controversial and differs based on pathology. Four centimeters is arguably the cut-off at which enucleation should be performed due to increased risk of recurrence of lesions greater than 4 cm [9,12,15]. Data suggest that this size limit may be increased to 6 cm in SCN and MCN without increasing recurrence, morbidity, or mortality [17]. Multifocality is a relative contraindication due to an incremental risk of pancreatic fistula with each enucleation. Depth of the cyst is also a relative contraindication for enucleation. More extensive dissection is required for deeper lesions. making their dissection more tedious and, at times, making formal resection the more appropriate choice [11,16,18].

Surgical Technique

Pancreatic cyst enucleation can be performed minimally invasively (laparoscopically/robotically) or open, based on surgeon preference. Minimally invasive enucleation has been more commonly performed in recent years and is associated with shorter operative and recovery times, less blood loss, and similar morbidity and mortality as open enucleations [14,19,20]. The steps of the procedure remain the same regardless of whether minimally invasive or open techniques are used.

After entrance into the abdomen, the liver, hemidiaphragms, and all peritoneal surfaces are surveyed for occult metastatic disease. Intraoperative ultrasound is used to identify intraparenchymal metastases, thus completing the survey of the liver. The pancreatic cyst is then exposed using the Kocher maneuver for head lesions, and entrance into the lesser sac for body and tail lesions. Ultrasound can again aid in both locating the cyst and careful characterization of the cyst. The distance between the cyst and the main pancreatic duct can be calculated to determine the safety of performing enucleation. Concerning features such as mural nodules and solid components can be identified with intraoperative ultrasound. After ultrasound evaluation, enucleation may be aborted due to suspicion for malignancy or duct proximity.

Superficial lesions with extrapancreatic components are the most amenable to cyst enucleation, as significantly less dissection is required to free them from surrounding parenchyma. Ultrasound guidance can assist in locating deeper lesions. Overlying parenchyma is dissected away until the lesion is identified. Frozen section pathology is always performed and if invasive disease is discovered, lymph nodes must be retrieved and negative margins achieved for maximal survival benefit. Parenchyma sparing must be balanced against, but never compromise, oncologic principles. The role of sentinel lymph node biopsy in treatment of biliary and pancreatic disease has recently been discussed in the literature, and may be useful for patients with unclear diagnoses or those benign lesions at higher risk for recurrence, particularly in young patients [21–23]. BD-IPMN have communicating ducts that must be identified and ligated to prevent leaks (Figure 94.2).

After removal of the cyst, the cavity is searched for small vessels and ducts which are ligated with clips, ties, or tissue coagulation devices. Thermal injury can result from cautery and should be avoided when the main duct

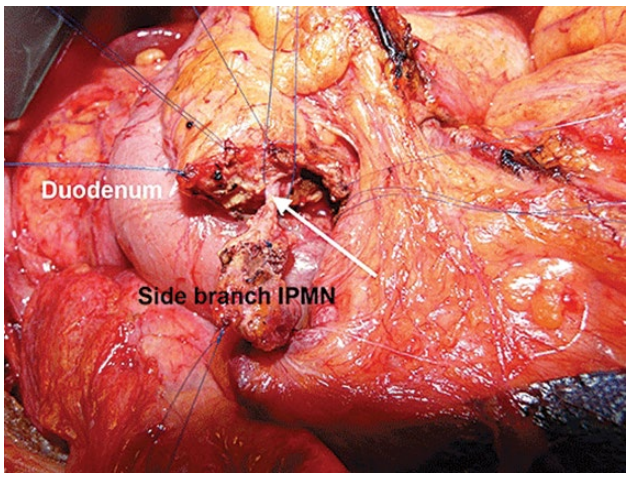

Figure 94.2 Intraoperative photograph of a BD-IPMN. The arrow identifies the communicating duct. *Source:* Turrini O et.al (2011) / Reproduced with permission Elsevier Inc.

is near. Main pancreatic duct integrity can then be evaluated with ultrasound and secretin stimulation. Some surgeons close the pancreatic parenchyma with absorbable suture on a large but fine needle, taking care to avoid any prominent vessels [24], and many routinely leave surgical drains. When the resected pancreatic bed measures >3 cm in diameter or when a main pancreatic duct injury is suspected, a Roux-Y loop to drain the wounded area may be considered [6,25].

Postoperative Management

Postoperative management of patients following cyst enucleation is the same as for any pancreatic resection. If surgical drains are placed intraoperatively, drain amylase should be followed. Drain amylase should be measured on postoperative day (POD) #1 [7]. Drain amylase elevated greater than three times the serum level indicates a pancreatic fistula [26]. Growing evidence suggests that in patients with low POD #1 drain amylase levels, drain removal by POD #3 dramatically reduces the incidence of a pancreatic fistula [27,28].

Management of pancreatic fistulas depends on grade and surgeon preference. No standardized management plan exists due to lack of strong evidence. Treatment of diet ranges from continued normal diet to nothing by mouth with total parenteral nutrition [7]. Other management options include endoscopic pancreatic sphincterotomy. This method has been practiced in patients with prolonged pancreatic fistula and may lead to improved healing time due to the decreased duct pressure [29].

Parenteral octreotide has been used by some surgeons in the immediate postoperative period to decrease the rate of pancreatic fistula [7,10]. A Cochrane review revealed a decreased rate of overall fistulas but no decrease in mortality, hospital stay, or rate of reoperation, and whether this difference holds for clinically relevant (grade B or C) pancreatic fistulas is unclear [30]. Those prescribing prophylactic octreotide endorse seven days of use. The authors of the Cochrane review recommend routine use in patients undergoing pancreatic resection because the potential benefit outweighs the low risk and low cost of the medication. However, a recent review by Vollmer et al. demonstrated that octreotide may increase the rate of pancreatic fistula [31]. Thus, the clinical role of octreotide in the prevention of pancreatic fistula remains controversial.

Postoperative Complications

Clinically relevant postoperative pancreatic fistula (CR-POPF) is the major morbidity following enucleation and occurs in 20% (range 9–41%) of cases (see Table 94.4). CR-POPF can be difficult to treat due to its many associated problems. Intraabdominal infection and/or hemorrhage, delayed gastric emptying, increased hospital stay, increased readmission, and the need for reintervention have all been associated with pancreatic fistula [18].

Specific risk factors for development of pancreatic fistula include soft pancreatic texture with absence of fibrosis, main pancreatic duct (MPD) diameter of less than 3 mm, cyst distance less than 2 mm from the duct, and cyst depth of greater than 3 mm (Table 94.3) [13–16]. Recently, Duconseil et al. found that tumor location in the inferior portion of the pancreatic head and uncinate process was an independent predictor of pancreatic fistula development, including clinically relevant (grade B or C) fistulas [32]. Other independent risk factors for fistula formation following enuclation include advanced age, New York Heart Association (NYHA) class II or III, recent episode of acute pancreatitis, and procedure time greater than 180 minutes [18,25].

Table 94.3 Risk factors for pancreatic fistula following cyst enucleation.

Soft texture
Pancreatic duct diameter <3 mm
Distance of cyst from pancreatic duct <2 mm
Cyst depth >3 mm
Recent episode of acute pancreatitis
NYHA class II or III
Operating room time >180 min
Lesion located in inferior pancreas or uncinate process

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Multiple studies have attempted to identify methods for decreasing the risk of fistula. In addition to the previously described prophylactic octreotide, a study by Kiely et al. demonstrated a decreased fistula rate (50% to 27%) by adding intraoperative ultrasound and closure of the space after cyst removal [24]. Preoperative nasopancreatic stenting is another approach that allows surgeons to palpate and directly visualize the duct, therefore avoiding MPD injury and fistula formation [18]. In addition, measurement of drain fluid amylase on POD #1 with drain removal by POD #3 will reduce the rate of CR-POPF [27].

Outcomes

Table 94.4 displays contemporary pancreatic cyst enucleation outcomes from major studies conducted since 2011. Overall morbidity and mortality of cyst enucleation have been reported to be 12–67% and 0–1% (with one exception), respectively, over the last decade. Many studies have demonstrated no statistical difference in morbidity or mortality when compared to formal resection [5,6,33–36]. However, a recent study by Beane et al., employing the American College of Surgeons National Quality Improvement Program (ACS-NSQIP), showed that cyst enucleation led to decreased morbidity and mortality when compared specifically to pancreatoduodenectomy, particularly with regard to delayed gastric emptying, surgical site infection, and sepsis [4]. Additionally, enucleation has consistently been shown to be associated with shorter operative time, less surgical blood loss, shorter ICU stay, and decreased postoperative endocrine and exocrine insufficiency when compared to formal resection. Patients undergoing enucleation also utilize fewer healthcare resources. Tumor recurrence and long-term survival also appear to be similar between the two groups [5,6,33–35].

Giuliani et al. recently compared quality of life metrics in patients after enucleation to healthy controls from the general population, and saw similar quality of life responses in almost all functional and symptom scales, except for those regarding "worries for the future" and "body image" [37].

The majority of recent studies have not demonstrated a difference in rate of postoperative pancreatic fistulas after enucleation compared to formal resection, when considering both all fistulas and clinically relevant (grade B or C) fistulas. The incidence of postoperative fistula after enucleation has ranged from 20% to 63% for all grades and 9–41% for grades B and C only. Jilesen et al. in particular reported a higher rate of clinically relevant pancreatic fistulas after enucleation of small PNETs when compared to pancreatoduodenectomy. The authors posited that this finding may have been due to a higher proportion of unfavorable pancreatic texture or due to proximity to the main pancreatic duct, both of which are known risk factors for fistula development (see Table 94.3) [35]. However, patients with higher grade fistulas after enucleation may need fewer invasive interventions, as Beane et al. reported fewer percutaneous drainage procedures following enucleation when compared to pancreatoduodenectomy (13.4% vs 22.4%) [4].

Cyst Ablation

Pancreatic cyst ablation is an alternate treatment option in which cysts are lavaged with ethanol or a chemotherapy solution, or ablated with radiofrequency alone. Potential candidates for cyst ablation are high-risk surgical candidates, those with a life expectancy of 3–5 years, or those who refuse surgery [8,38]. Ablation also may be used as a bridge to surgery when patients are already receiving EUS with FNA for indeterminate lesions [39]. Patients with coagulopathies should not undergo ablation as passage of the needle into the cyst may cause bleeding. Most endoscopists use the cut-off of international normalized ratio (INR) less than 1.5 and platelets greater than 50 000 [39,40]. Lesions that are consistent with a benign cyst by clinical, radiologic, cytologic, and chemical evaluation should not undergo ablation [38].

The procedure begins with a complete endoscopic ultrasound exam. The cystic lesion is located and characterized. Cysts must be greater than 2 cm in order to safely target. Multiple septations are another barrier to ablation. If the cyst contains multiple septations in which not all compartments communicate, complete drainage will not be possible. Unilocular or oligolocular cysts with 2–6 compartments are therefore preferred [38,39,41]. The main pancreatic duct should be carefully evaluated to confirm absence of communication with the cyst. The ablative agent will be lost through the communicating duct if the cyst is connected to the main duct [40]. Some authors advocate preoperative ERCP to determine the cyst's ductal relationship [39]. Intraoperative ultrasound also can serve as a final opportunity to diagnose overt cancers with peripancreatic invasion. Ablation may then be aborted.

Following a complete intraoperative ultrasound examination, a needle (22 gauge for cysts 2–3 cm, 19 gauge for cysts >3 cm) is passed transduodenal or transgastric into the cyst [38]. This passage is done under direct ultrasound guidance. The cyst is then aspirated until collapse. If the cyst fluid is thick and mucinous, the clinician may be unable to complete cyst aspiration [39]. Cyst fluid is used for cytology analysis and measurement of carcinoembryonic antigen (CEA) and amylase concentrations.

If this analysis or ultrasound characterization is consistent with invasive cancer, formal pancreatic resection should be considered. With the cyst collapsed, 80% or 99% ethanol is injected into and aspirated from the cyst for 3–5 minutes with a volume equal to the volume of cyst fluid initially removed [38,40]. If the cyst is in communication with the main pancreatic duct as previously described, the ablative solution will not remain in the cyst during this time. Following ethanol lavage, a chemotherapeutic agent, most commonly paclitaxel, may also be infused into the cyst, again with a volume equal to the original cyst fluid aspirated [38,41].

Existing literature is heterogeneous with varying rates of cyst resolution, 33–85% [39–42]. Higher rates of resolution have been reported with the combined use of ethanol and chemotherapy agents [39, 41]. Recently, the CHARM trial, a randomized, double-blinded pilot study, demonstrated that an alcohol-free approach may be similarly effective with an improved side-effect profile [43]. A larger, NIH-funded, multicenter randomized control trial is currently ongoing to further investigate this finding [44]. Additional studies have shown greater decrease in size and higher rates of cyst resolution with multiple ablation sessions [41]. Resolution is most often based on radiographic evidence as shown in Figure 94.3 [40]. Resolution may be dependent upon cyst type, with mucinous cysts having much lower rates of resolution [42]. Other potential predictive factors of complete response include locularity, presence of mural nodules, and cyst size <35 mm [45].

Cysts which achieve complete resolution appear to have a low risk of recurrence. Limited longitudinal data so far have demonstrated 0–2% recurrence, although further studies are still needed [45,46]. While uncommon, multiple complications have been reported. Fever, abdominal pain or acute pancreatitis occurs in 2–10%. Intracystic hemorrhage, bowel perforation, and severe acute pancreatitis are even less commonly reported [39,40,42].

Radiofrequency ablation is another recently described technique for managing select pancreatic lesions [41]. A recent prospective trial of 30 patients demonstrated a 10% complication rate; however, the most serious adverse

events of severe acute pancreatitis and jejunal perforation only occurred in the first two patients. The protocol was then modified to include prophylactic measures and cyst fluid aspiration prior to radiofrequency application, and no further adverse events were reported in the remaining 28 patients [47]. Since then, several studies have investigated the effectiveness of this modality in various pancreatic lesions, and reported response rates have ranged from 65% to 86% [47–49]. However, data on the long-term outcomes of this approach are still evolving.

Conclusion

Pancreatic cyst enucleation is an alternate surgical option for small, low-risk cystic lesions. Several factors make each pancreatic cyst more or less optimal for enucleation. Main duct involvement or close proximity increases the rate of postoperative fistula development. Enucleation of large, multifocal, or tail cysts does not yield significant parenchymal preservation and therefore is not beneficial. Patients considered for enucleation must receive appropriate preoperative evaluation and must be adequately fit. Postoperative pancreatic fistula is the major morbidity of enucleation but occurs at the same rate as in formal resection. Enucleation is associated with less utilization of healthcare resources and similar or lower morbidity and mortality without compromising local recurrence rates or long-term survival.

Lastly, cyst ablation is an alternate technique that may be employed in patients unwilling or unable to tolerate enucleation or resection.

Duodenum-preserving Pancreatic Head Resection and Local Extirpation of SPTP in Children and Adolescents: Indications and long-term results

Jiri Snajdauf, Michal Rygl, Barbora Kucerova, and Natalia Newland

Department of Pediatric Surgery, 2nd Faculty of Medicine, Charles University, University Hospital Motol, Prague, Czech Republic

Introduction

Solid pseudopapillary tumor of the pancreas (SPTP) was first described by Frantz in 1959 [1,2]. Since then, various names have been used to describe this unusual lesion, such as solid and cystic tumor of the pancreas, papillary-cystic and solid tumor of the pancreas, solid and papillary epithelial neoplasm.

Solid pseudopapillary tumor of the pancreas is a rare tumor and typically shows a benign clinical course with a low malignant potential. Although some cases may be locally aggressive and infiltrative, metastases to liver, lung, and skin occur very rarely. Little is known about the origin and histogenesis of this tumor. The fact that SPTP tumors may express epithelial as well as mesenchymal markers and occasionally show both exocrine and endocrine features suggests a stem cell origin [3]. Calcifications or internal septations are detected in some cases. The neoplasm is generally encapsulated and is well demarcated from the remaining pancreas. The most useful biochemical markers in the diagnosis are α1-antitrypsin, α1-antichymotrypsin, neuron-specific enolase, and vimentin.

The tumor occurs predominantly in girls and young women in their second or third decade of life.

Symptoms, when they occur, are often vague and nonspecific and include abdominal pain and palpable mass. About 50% of SPTPs are larger than 5 cm at the time of diagnosis. Some children with SPTP can manifest after abdominal blunt trauma [4]. In the series published by Snajdauf et al., four out of 28 patients with SPTP presented after blunt abdominal trauma (14%) [5,6].

Imaging methods used to diagnose SPTP include abdominal ultrasound, spiral computed tomography (CT), and magnetic resonance imaging (MRI). Characteristic images show a large, round, well-encapsulated, combined cystic and solid mass. The differential diagnosis of SPTP includes any cystic and/or solid pancreatic process, e. g., congenital pancreatic cysts, hemorrhagic pseudocyst, and other common cystic neoplasms of the pancreas, such as serous cystadenoma, mucinous cystic neoplasms or pancreatoblastoma.

Solid pseudopapillary tumor of the pancreas is a surgically curable tumor with an almost uniformly good prognosis. Pancreatic resection including pancreaticoduodenectomy and distal pancreatectomy is the standard of care for SPTP in children [7–16]. Tumor enucleation alone is not recommended as it will not provide a radical surgical management and does not prevent recurrence [17]. Distal pancreatectomy is performed for tumors in the body or tail of the pancreas, and pancreaticoduodenectomy for tumors of the pancreatic head. In cases of a tumor of the head of the pancreas, most pediatric surgeons would perform a modified Whipple duodenopancreatectomy [7–16] or Frey procedure [18–22]. However, the preferred surgical option for pediatric patients is Beger's operation – the duodenum-preserving head resection [23].

Duodenum-preserving Technique of Head Resection of the Pancreas in Children

The duodenum-preserving head resection of the pancreas (DPHRP) described in 1980 by Beger and colleagues and the extended pancreaticojejunostomy with conization of the pancreatic head described in 1987 by Frey represent new approaches to proximal inflammatory lesions and benign tumors [19,23]. These operations are recommended for adult patients with severe chronic pancreatitis and inflammatory enlargement of the head of the pancreas in cases of medically intractable pain,

stenosis of the common bile duct, severe obstruction of the duodenum, or compression of the portal vein causing portal hypertension.

The surgical technique of DPHRP includes two major steps: first, total or subtotal resection of the head of the pancreas, preserving the duodenum; second, restitution of the exocrine pancreatic secretory flow from the body and tail of the pancreas using the first jejunal loop as an interposition. After an abdominal exploration through a transverse oblique muscle cutting incision in the right hypochondrium, the lesser sac is entered via the gastrocolic omentum and the anterior aspect of the pancreatic head is fully exposed. The Kocher maneuver is generally not necessary and is not performed in order to preserve mesoduodenal vessels. After the identification, ligation, and division of the anterior superior and anterior inferior pancreaticoduodenal artery and vein (ASPDA, AIPDV) (Fig. 95.1), resection of the head is performed mostly using an ultrasonic aspirator and dissector (Cavitron System 2000, Valley Lab) (Fig. 95.2). When the tumor spares the part of the gland adjacent to the first, second, and third parts of the duodenum, a 3–5 mm thick rim of pancreatic tissue is left *in situ* together with the capsule. During resection of the uncinate lobe, the superior mesenteric artery and vein are carefully and meticulously mobilized. The intrapancreatic portion of the distal common bile duct and the origin of the posterior superior pancreaticoduodenal artery (PSPDA) are identified and preserved. These vessels together with other posterior pancreatoduodenal vessels lie on a connective tissue membrane.

Preserving the membrane and thus the blood supply to the duodenum is one of the most important aspects of this procedure. Kimura examined the topography of the duodenum, pancreas, bile duct, and supplying vessels using

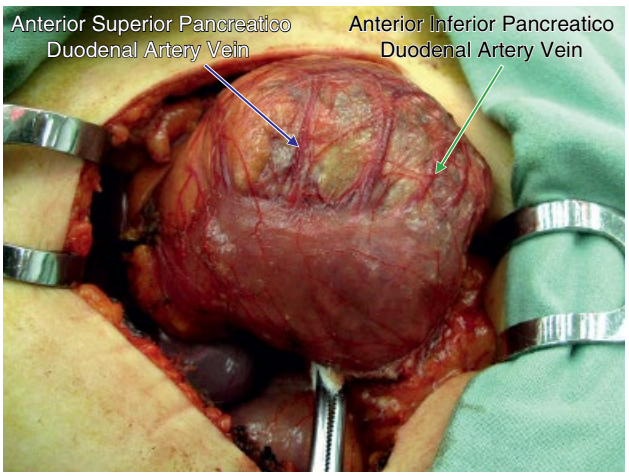

Figure 95.1 Ligation and division of the anterior superior and anterior inferior pancreaticoduodenal artery and vein (ASPDA, ASPDV, AIPDA, AIPDV).

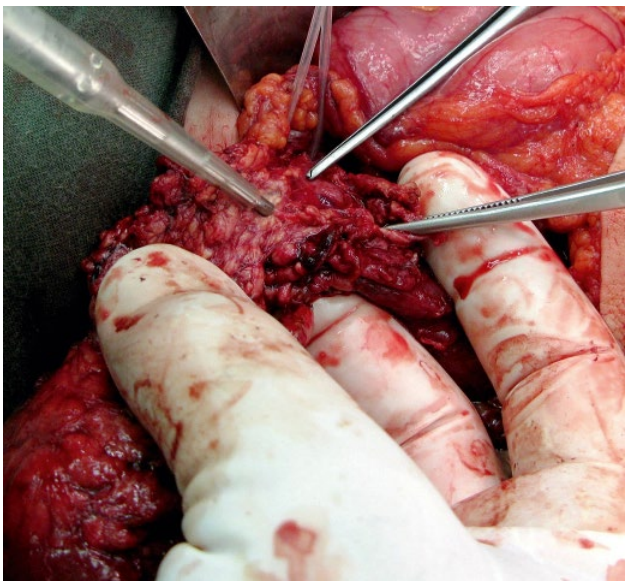

Figure 95.2 Resection of the head is performed using an ultrasonic aspirator and dissector (Cavitron System, Valley Lab, USA).

autopsy materials in 40 cases and also concluded that it is important to preserve the posterior superior and posterior inferior pancreaticoduodenal artery and vein [24].

During ultrasonic excavation of the head of the pancreas, meticulous care has to be taken to properly identify and not injure the bile duct (Fig. 95.3). The pancreatic duct is transected near the ampulla. The resection itself is performed at the level of the mesenteric vein, or more laterally if the tumor involves part of the body as well. The rest of the gland is drained into the jejunum by means of a retrocolic single end-to-end, Roux en-Y pancreaticojejunostomy (Fig. 95.4). A single-layer anastomosis is performed between the pancreas and the jejunal loops with absorbable sutures [5,6].

In summary, the principle of the Beger operation is a subtotal resection of the head of the pancreas leaving a small part of the head of the pancreas close to the duodenal wall, while preserving the duodenum and distal common bile duct [21]. In comparison to the Whipple procedure, the DPHRP spares the patient a gastric resection, a duodenectomy, and a common bile duct resection. The procedure represents one of the new approaches to treating proximal inflammatory lesions and tumors [25–27].

Complications

Complications after DPHRP and distal pancreatectomy for SPTP are relatively rare and similar in children and adults. Possible complications are bile duct stricture and fluid collection which can be managed conservatively by balloon dilation and percutaneous drainage, respectively.

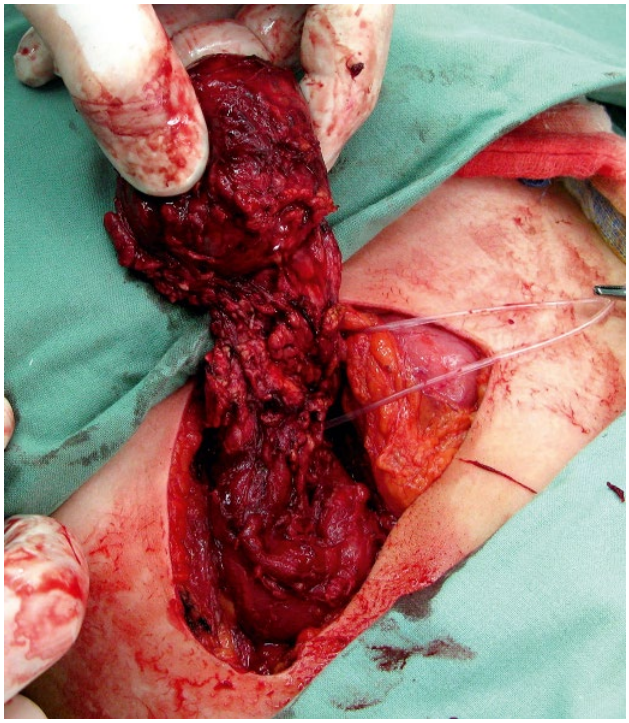

Figure 95.3 The head of the pancreas with the tumor.

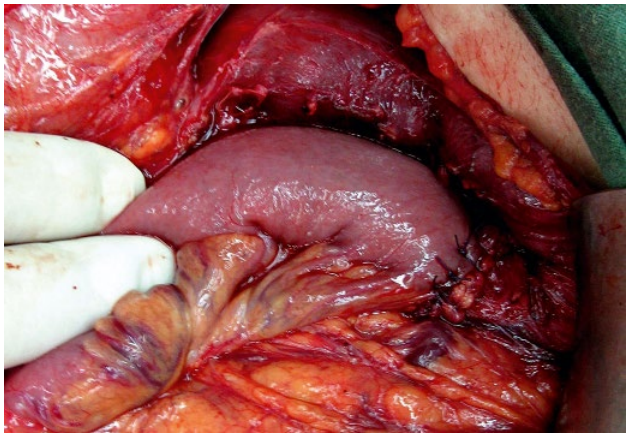

Figure 95.4 The rest of the pancreas is drained into the jejunum by means of a retrocolic single end-to-end Roux en-Y pancreaticojejunostomy.

Other reported complications include pancreatic fistula, wound infection, pancreatic duct stenosis, delayed gastric emptying, abdominal pain, pancreatiti,s and exocrine pancreatic insufficiency [28,29].

Recurrence

Larger tumors (diameter >5 cm), lymphovascular invasion, lymph node metastasis, synchronous metastasis, and positive margin increase the risk of postoperative recurrence of pancreatic SPN. Due to the low but actual malignant potential, all SPTPs should be excised, which could provide positive prognoses [30–32].

Metastases

Approximately 6% of all SPTPs are reported to invade surrounding organs and about 10–15% develop distant metastases. Occasionally, the tumor may spread to the liver, lung, or lymph nodes. The most common metastatic organ is the liver, into which tumor cells metastasize through either the superior mesenteric vein or the portal vein. The treatment of liver metastasis most commonly involves liver resection. Pulmonary metastases are extremely rare [33–36].

Long-term Follow-up in Children

The survival rate in children after DPHRP and distal pancreatectomy for SPTP is higher than 95%, but pancreatic surgery may result in impaired exocrine and endocrine pancreatic function. Currently, only limited data are available on long-term pediatric pancreatic function following surgical resection. Careful and long-term monitoring should follow any pancreatic surgery in order to recognize and promptly treat exocrine and endocrine pancreatic insufficiency, which can occur in 12–25% of patients after surgery [37]. According to a large population-based database, the rates of postpancreatectomy endocrine (diabetes) and exocrine insufficiency in adults were 40% and 35%, respectively. Exocrine insufficiency is defined by the use of pancreatic enzyme replacement [38]. New onset of diabetes in children after pancreatic resection of SPTP was reported in 5–10% of cases [39]. The authors' experience is summarized in Table 95.1.

The duodenum-preserving technique discussed above has an important role for the developing child with a life expectancy of at least 7–8 decades. A procedure resulting in minimal interference with normal gastrointestinal function and causing no or minimal long-term discomfort should be proposed for these patients. The duodenum and common bile duct sparing resection of the head of the pancreas is a highly effective surgical procedure with low early and late morbidity and no mortality as published in the series by Snajdauf et al. It ensures total removal of pathologic tissue of the SPTP of the head of the gland, as shown by the fact that there was no local recurrence in their study [5,6]. The duodenum-preserving resection of the head of the pancreas should be the procedure of choice in pediatric SPTP.

Introduction

With the increased routine usage of high-resolution cross-sectional imaging and thus increasing identification of cystic neoplasms (CN) of the pancreas, often as incidental findings, surgical resection of CN has become part of the daily routine in specialized centers.

Cystic lesions of the pancreas represent a very heterogeneous group of tumors. Intraductal papillary mucinous neoplasms (IPMN) represent about 35% of all CN of the pancreas and about half of the resected ones [1], with different potential for malignant transformation depending on a number of variables, including patterns of duct involvement (main duct [MD], branch duct [BD], mixed type) and epithelial subtypes, amongst others [2,3]. Further CN with potential for malignant transformation include mucinous cystic neoplasms (MCN) and solid-pseudopapillary neoplasms (SPN). SPN are very rare tumors with a reported five-year overall survival rate of 94–97% and a rate of recurrence of 4% [4]. MCN are mostly solitary and thus complete resection is often curative [5,6].

The follow-up and surveillance strategy for patients after resection of an IPMN in contrast to other CN, however, remains a matter of debate, which is mainly due to the fact that their natural history varies widely. The possibility of progression to an invasive carcinoma for some IPMN, as well as the risk of a synchronous or metachronous pancreatic ductal adenocarcinoma (PDAC) in patients with known IPMN, is well known. The publication of the 2015 American Gastroenterological Association (AGA) Institute Guideline explicitly suggesting against routine surveillance of resected CN without high-grade dysplasia (HGD) or malignancy has thus sparked a controversial discussion on the appropriate postoperative management of these lesions [7]. Consequently, the International Association of Pancreatology (IAP) established an updated consensus guideline in 2017 [6,8] and the European evidence-based guidelines [9] and the American College of Gastroenterology (ACG) clinical guideline [10] were published, all three explicitly addressing the postoperative management of resected IPMN.

In terms of recurrence of an IPMN, there are different scenarios to be considered. Traditionally, recurrence has been used in the context of malignancy and in the case of IPMN would therefore describe the recurrence of an IPMN-associated invasive cancer after curative resection. However, in most cases, patients with IPMN present with multifocal disease and thus residual or metachronous developed lesions in the pancreatic remnant initially not meeting the criteria for resection may either stay stable, progress into IPMN meeting those criteria or even develop into PDAC. Especially with the establishment of parenchyma-sparing techniques for IPMN [11], it is extremely important to bear those different settings in mind when releasing patients into postoperative care.

This chapter will focus on the risk of recurrence for IPMN of the pancreas as well as appropriate surveillance strategies.

The Pancreatic Remnant

IPMN are believed to represent a part of the so-called "field defect," meaning that the entire ductal system of the pancreas is at risk of developing dysplasia and not only the radiographically detectable lesion [6,12]. Thus, the remnant gland is predisposed to developing significant neoplasia even after resection of the primary lesion.

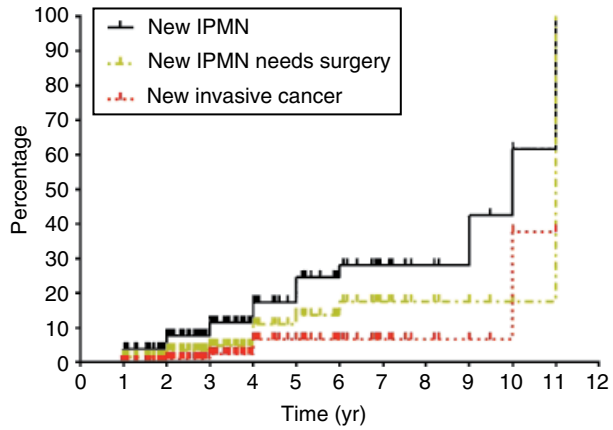
Recurrence rates for resected IPMN are between 9% and 14% [13–15]. For invasive IPMN, Kim et al. reported a recurrence rate as high as 34% in their cohort of 117 invasive IPMN out of 548 resected IPMN [14], which is in accordance with their previously published analysis of 366 resected IPMN [13]. For their 431 patients with noninvasive IPMN resected between 2000 and 2018, the reported recurrence rate after resection was 1.7% (6/353) and 5.1% (4/78) for low-grade (LGD) and HGD, respectively [14]. For resected patients between 1995 and 2014, Kang et al. reported a recurrence rate of 5.4% for 298 resected non-invasive IPMN [13]. Importantly, in both analyses, distant recurrences or pancreatic cancer occurred after resection of noninvasive IPMN in two and seven cases, respectively. However, it is important to note that distant metastases from other organ malignancies were not excluded in either analysis.

Marchegiani et al. analyzed 299 patients with noninvasive IPMN and reported a recurrence rate of 9% after surgical resection. Importantly, they found that 2% of these recurrences presented as invasive cancer. Further, MD-IPMN recurred more often as invasive cancer (5/6) than BD-IPMN (1/22) did [16]. This is in line with other literature reporting recurrence rates of resected noninvasive IPMN ranging from 1% to 20% and a recurrence rate of secondary invasive lesions between 2% and 7% [17–23].

However, the five-year recurrence-free survival rate (RFS) has been reported to be favorable, ranging from 77% to 100% (Table 96.1). The median time to recurrence has been described to range from 15 months to 4.5 years, stressing the necessity for long-term surveillance as has recently been recommended by several authors.

Two comprehensive analyses evaluating the natural history of the pancreatic remnant after resection of a noninvasive IPMN were published by the Johns Hopkins group. In 2013, an analysis of 130 patients undergoing resection of noninvasive IPMN was reported by He et al. with a one-, five-, and 10-year risk of developing a new IPMN of 4%, 25%, and 62%, respectively, with the chance of requiring surgery being 1.6%, 14%, and 18%, respectively [24]. Importantly, the risk of developing invasive cancer at one, five, and 10 years was found to be 0%, 7%, and 38%, respectively (Fig. 96.1) [24]. At a median follow-up of 60 months, all patients who were found to have invasive carcinoma on completion pancreatectomy remained alive with no evidence of recurrent disease.



In 2020, the same cohort was reevaluated with a prolonged follow-up time and focus on the identification of risk factors for recurrence [12]. At a median follow-up of 9.5 years, clinically relevant recurrence was now observed in 15% of patients with a three- and five-year RFS rate of 95% and 86%, respectively. Importantly, 14 of 19

recurrences were detected after three years and six recurrences after five years. Further, 13 of those 19 patients recurred as a PDAC. These two studies thus underline the importance of indefinite surveillance after resection of noninvasive IPMN, because of these long-term risks.

It is important to mention the possibility that the invasive cancer recurrences could represent concurrent PDAC that were undetected at the time of surgery instead of the metachronous development of a new invasive adenocarcinoma. However, the fact remains that these patients still require long-term surveillance.

Predictors of Recurrence

Identification of predictors for postsurgical recurrence for noninvasive IPMN is essential to guide postoperative surveillance strategies. Three main factors have been subject to discussion as predictors of postsurgical recurrence in recent years.

In the Johns Hopkins series, He et al. identified family history as an independent predictor for postsurgical recurrence in their initial analysis [24], which was later confirmed in the same cohort with long-term data by Pflüger et al., who reported family history of pancreatic cancer as an independent risk factor for recurrence in uni- and multivariate analysis (adjusted hazard ratio [aHR] 3.05, 95% confidence interval [CI] 1.17–7.94, P = 0.023) [12]. Further, the group from the Massachusetts General Hospital reported that a higher number of patients with family history of pancreatic cancer died of metastatic or recurrent disease than those without family history (72.7% versus 45.1%). However, they also found an increased incidence of concomitant PDAC (11.1% vs 2.9%, P = 0.02) as well as of extrapancreatic malignancies (35.6% vs 20.1%, P = 0.03) in patients with a positive family history of pancreatic cancer [25]. Thus, it remains unresolved in this analysis whether the observed difference in survival is due to the recurrence of the IPMN or the concurring PDAC [25].

Interestingly, an analysis of 315 surgically resected IPMN showed that 7.3% of patients had an underlying germline mutation associated with cancer risk and 2.9% had a germline mutation in a known pancreatic cancer susceptibility gene [26], which is similar to the rate of germline mutations found in sporadic PDAC patients [27]. Also, IPMN patients with a germline mutation in a susceptibility gene were observed to have a significantly higher likelihood of concurrent PDAC than those without a germline mutation.

In summary, patients with a family history of pancreatic cancer represent a high-risk cohort that should be closely monitored after surgical resection of the index lesion. Also, given the association with extrapancreatic malignancies in patients with family history of pancreatic cancer, these patients should be encouraged to participate in established age-appropriate cancer screening programs. Further, germline testing in selected IPMN patients may have value in postsurgical risk stratification.

For HGD as a postsurgical risk factor, the literature is quite consistent. The Johns Hopkins group reported a recurrence rate of 21% in patients with HGD in the resected lesion, which was, however, not significantly different to those with LGD (22%) nor those with intermediate-grade dysplasia (IGD) (14%) [24]. Importantly, though, three patients in their cohort with a recurrence of PDAC had HGD in their primary specimen.

In an analysis of 100 patients with HGD IPMN, the postsurgical recurrence rate was found to be 9%, median time to recurrence was 15 months and 3% patients developed invasive recurrences [23]. Similarly, the Seoul National University group found a significant association between pathological dysplasia and rate of recurrence (P = 0.021) and confirmed HGD as well as invasive IPMN as independent predictors of recurrence [13]. In their updated analysis of the same cohort, Kim et al. reported the five-year disease-free survival according to pathology as 88.7%, 83%, and 45.5% for LGD versus HGD versus invasive pathology, respectively [14]. Also, upon reevaluation of their 2013 cohort, the Johns Hopkins group identified high-grade IPMN as an independent risk factor for postsurgical recurrence on uni- and multivariate analysis (aHR 1.88, 95% CI 1.17–3, P = 0.008) [12]. In a separate analysis of 140 patients, the group reported

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

that patients with HGD in their primary resected IPMN were more than eight times more likely to subsequently develop invasive cancer (odds ratio [OR] 8.82, 95% CI 2.56–30.43, P = 0.001) [28]. Consequently, there is no question that patients with HGD in their resected specimen are prone to recurrences and also at risk of invasive recurrences. Thus, this cohort, as a high-risk group, needs to be kept under close surveillance.

The factor that has initiated the most controversy in terms of impact on postsurgical recurrences is that of the surgical margin as conflicting outcomes continue to be reported by different centers. The Johns Hopkins Group [12,24] as well as Kang et al. [13] reported no differences in recurrence rates in margin-positive patients compared to margin-negative patients (16.7% vs 10.2%, P = 0.421). Similarly, in a multicenter analysis of 502 noninvasive IPMN, Dhar et al. found margin positivity not to be associated with recurrence of the remnant pancreas. In their analysis, margin positivity was mainly due to LGD [20].

In contrast, a report from the Memorial Sloan Kettering group reported that dysplasia of any degree at the resection margin was a risk factor for recurrent disease in the remnant gland (OR 2.9, P = 0.02), but not for recurrent disease at the resection margin itself [22]. Further, Marchegiani et al. reported a significantly higher rate of recurrence in patients with positive margins (25% vs 14%, P = 0.008). In their analysis, margin status was identified as a strong independent predictor of recurrence on multivariate analysis (HR 2.6, P = 0.0046) [29]. Also, the updated analysis of the Seoul National University group by Kim et al. identified HGD and invasive pathology at the resection margin to be significantly associated with recurrences (P = 0.036) [14]. HGD margins had a five-year cumulative recurrence rate of 4.3% compared to 0.7% for LGD. Taken together, HGD and invasive pathology at the resection margin had a significantly worse cumulative five-year recurrence rate of 50.6% compared to 5.9% for LGD and 8.3% for R0 resection.

The discrepant findings are likely to be a result of the retrospective nature of underpowered studies in trying to analyze a small, specific subcohort of patients. However, even though reports are still diverse, in the case that invasive cancer and also HGD are found at the resection margin, additional resection to achieve negative resection margins is recommended by the current IAP guideline [8].

Concomitant Low-Risk Lesions

Only very few studies have examined the progression of lesions left in the pancreatic remnant after removal of the index lesion separately from newly developing lesions due to the inconsistent use of the terms "progression" and "recurrence" for synchronous or *de novo* developing lesions, respectively.

Miller et al. reported on 38 of 243 (20%) patients undergoing surgical resection for noninvasive IPMN with concomitant residual IPMN in the pancreatic remnant [17]. One of those patients developed invasive disease. The authors report a five-year progression-free survival of 88% for those patients compared to 83% in patients without a known remnant lesion (P >0.05). Moriya et al. reported on 14 of 203 (7%) patients with residual lesions in the pancreatic remnant after resection of an IPMN [30]. After a median follow-up time of 40 months, none of these lesions required surgical intervention. Similarly, in a study by Marchesini et al., 33 of 412 (9%) resected IPMN patients had residual BD-IPMN in their pancreatic remnant, none of which met criteria for resection after a median follow-up of 58 months.

Further, in an analysis from the Memorial Sloan Kettering Cancer Center 49 of 319 (16.2%) patients resected for non- or microinvasive IPMN were identified as having residual lesions in the remnant pancreas not meeting surgical resection criteria at the time of the index operation [31]. Importantly, residual lesions in the pancreatic remnant were not significantly associated with an increased risk of progression on univariate analysis.

Furthermore, Lee et al. analysed 103 patients with BD-IPMN under surveillance not meeting the criteria for resection. During a median follow-up of 51.5 months, 43 (40.2%) patients had progressive disease, 21 of which presented with cancerous changes [32], and 32 (29.9%) patients required surgery. Similarly, Del Chiaro et al. surveyed 395 patients with BD-IPMN without features indicating surgery [33]. In this cohort, the cumulative one-, four-, and 10-year risk of disease progression and the need for surgery were 11.2%, 70.6%, and 97.5% and 2.9%, 26.2%, and 72.1%, respectively. Median follow-up time was 932 days. IPMN-specific one-, five-,-, and 10-year survival rates were 100%, 100%, and 94.2%, respectively. Four patients died of pancreatic cancer. In 49 patients with BD-IPMN in whom indications for surgery existed but who could not be operated on for other reasons, one-, five-,- and 10-year IPMN-specific survival rates were 90.7%, 74.8%, and 74.8%, respectively, suggesting a fairly indolent nature of disease.

Both studies, however, confirm a significant risk for progression and the need for surgery over time even in cases of BD-IPMN that initially do not meet the criteria for surgical resection.

From the few available data, it seems that patients with synchronous lesions in the pancreatic remnant are not at any higher risk for recurrence or progression, justifying current practices of only operating on IPMN that meet criteria for resection. However, long-term surveillance is necessary due to the possibility of long-term progression (Fig. 96.2).

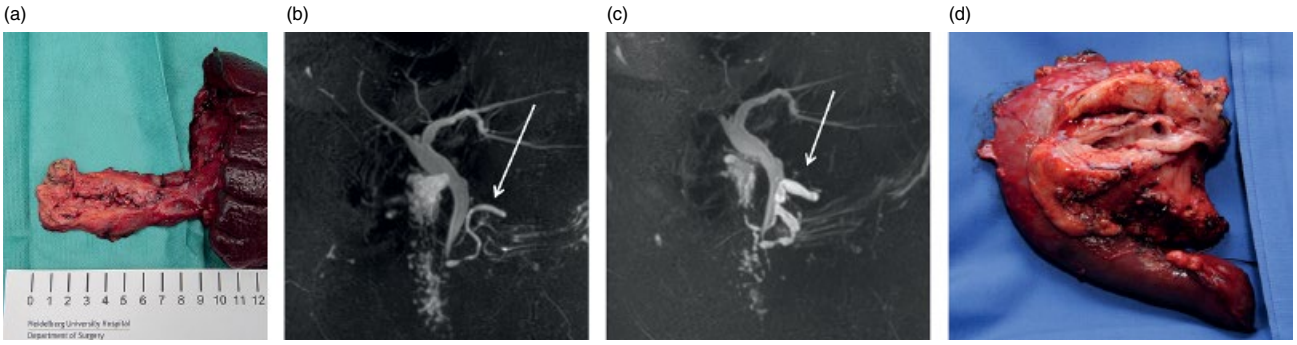

Figure 96.2 Malignant recurrence of disease in pancreatic remnant.

Postoperative Surveillance Strategy

Postoperative surveillance strategies aim at early detection of recurrent or progressive IPMN meeting criteria for surgical resection before invasive cancer occurs and thus improve long-term survival. Several guidelines with different strategies for postoperative surveillance of noninvasive IPMN exist.

As discussed above, there are at least three groups of "high-risk" patients in whom correlation with recurrence is likely to be higher than in other patients, namely those with a positive family history for pancreatic cancer, positive resection margin and HGD in the primary lesion. These patients should be monitored closely as the risk of development of high-risk lesions or invasive pathology is high. Further, as described above, time to recurrence can be up to five years after the index operation and all patients are at risk of developing invasive disease in the pancreatic remnant or extrapancreatic lesions requiring long-term surveillance. Furthermore, after partial pancreatoduodenectomy, an increase in diameter of the main pancreatic duct of the pancreatic remnant poses a radiographical challenge in differentiating between chronic obstructive pancreatitis and recurrent IPMN.

The 2017 IAP guideline [8], the European evidence-based guidelines on pancreatic cystic neoplasms [9], and the ACG guideline [10] recommend lifelong surveillance of all patients undergoing surgical resection of any IPMN as long as the patient remains fit for surgery.

The IAP guidelines recommend cross-sectional imaging at least twice a year for patients with positive family history, margin positivity for HGD and a nonintestinal subtype of resected IPMN, and every 6–12 months for all other patients. The modality of imaging is not specified.

The European evidence-based guidelines recommend surveillance of resected HGD or MD-IPMN every six months for the first two years, followed by yearly surveillance, whilst patients with LGD-IPMN should be followed in the same manner as nonresected IPMN patients (every six months for the first year, then yearly thereafter) and those with IPMN in the pancreatic remnant not meeting criteria for resection should be evaluated as nonresected BD-IPMN. The guidelines recommend MRI or EUS as the imaging modality of choice.

The ACG guidelines recommend a follow-up every six months with MRI or EUS for patients with resection of an HGD-IPMN and an MRI every two years for patients who had LGD or IGD in their IPMN. For patients with an IPMN in the remnant pancreas, recommendations for surveillance strategies are based on the size of the lesion.

In contrast, the AGA guidelines recommends an MRI scan every two years after resection of invasive disease or HGD. Further, they suggest against the routine surveillance of pancreatic cysts without HGD or malignancy at surgical resection [7]. In the light of the above discussion, both ACG and AGA recommendations do not seem to be sufficient as late long-term progression of IPMN is observed in both scenarios – under mere surveillance as well as postoperatively following partial pancreatectomy.

However, more research on the identification of both postoperative and preoperative predictors of recurrences, such as serum signatures [34], is needed in order to optimize modern treatment strategies for noninvasive IPMN. For selected elderly or frail patients with significant comorbidities in whom life expectancy is short or who would not be fit to tolerate pancreatectomy, follow-up after resection of a BD-IPMN may not be necessary.

Conclusion

The recurrence rate after resection of a noninvasive IPMN ranges between 1% and 20% with about 2–7% of invasive recurrences with a cumulative 10-year risk of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. developing indications for resection or invasive cancer of 18% and 38%, respectively. Early detection of progressive or recurrent IPMN before invasive cancer occurs improves long-term survival. The median time to recurrence can range up to five years after initial resection. Especially for patients with family history of pancreatic cancer, HGD in the resected specimen and positive resection margins present a high risk of recurrence also of invasive disease and should be monitored closely. All patients undergoing surgery for noninvasive IPMN should have lifelong surveillance, preferably with MRI or EUS. Age-appropriate cancer screening programs should be recommended due to the risk of extrapancreatic lesion development.

Long-term Outcome after Observation and Surgical Treatment of Cystic Neoplasms: What is the Evidence?

Roberto Salvia, Giovanni Marchegiani, Giampaolo Perri, and Claudio Bassi

The Pancreas Institute, G.B. Rossi Hospital, University of Verona Hospital Trust, Verona, Italy

Introduction

Incidentally discovered pancreatic cyst neoplasms (PCNs) represent a modern pancreatic "pandemic" as their prevalence among the general population is constantly rising due to the extensive use of cross-sectional imaging such as computed tomography (CT) scan and magnetic resonance imaging (MRI) [1,2].

Originally, their treatment consisted of an aggressive surgical approach, based on the role of intraductal papillary mucinous neoplasms (IPMNs) as precursors of pancreatic cancer [3,4] with high presumed risk of malignancy resulting from retrospective and uncontrolled historical data.

Only recently, new evidence from large observational studies has highlighted that most cases can be safely watched over time due to a low risk of malignant progression [5–9]. Therefore, the management of PCNs has evolved towards fewer patients undergoing operative resection and fewer benign lesions being resected.

Three main guidelines are available to help determine the management of PCNs, namely the International Association of Pancreatology, the European evidence-based guidelines, and the American Gastroenterological Association [10–12]. All of them tend to be consistent regarding the main indications for surgery, as selective resection of PCNs seems to be appropriate, balancing the risk of malignancy with the risks of an operation. However, current recommendations are still based on expert opinions and scientific evidence provided mostly by surgical series, explaining why available guidelines remain characterized by high sensitivity and low specificity, and consequently burdened by a high rate of surgical overtreatment. In patients undergoing resection, either at the time of diagnosis or after observation, the chance of cure, the incidence of tumor recurrence, and disease-specific or overall survival depend on the cyst type and the presence of an invasive component.

Guidelines tend to significantly diverge regarding indications for surveillance and surveillance discontinuation. Patients managed nonoperatively are enrolled in radiologic surveillance protocols, with the aim of finding signs of possible malignant degeneration. Surveillance protocols require periodic cross-sectional imaging and/or endoscopic ultrasound, at a high economic cost for the community. Furthermore, there is no ideal test to diagnose transformed PCNs, and there is not general agreement on the optimum method and timeframe for follow-up for these lesions. Long-term results of surveillance protocols are starting to be reported in the literature, especially for lesions amenable to initial observation, such as serous cystic neoplasms and branch-duct IPMNs (BD-IPMNs) [13,14]. The cost of observing thousands of patients is a relevant burden for healthcare systems, and an ideal target for safe surveillance discontinuation also represents an urgent issue [9]. This chapter describes the long-term outcomes after observation or surgical resection of PCNs.

Serous Cystic Neoplasms

The invariably benign nature of serous cystic neoplasms, combined with the morbidity and potential mortality of pancreatic resections, led to a conservative management strategy. The safety of nonoperative management and the generally slow growth rate of these lesions have been extensively demonstrated [15,16]. A critical review of their pathologic features revealed the misinterpretation of the few cases reported as malignant in literature [17]. The optimal interval between follow-up imaging tests in pancreatic serous cystic must be tailored based on cyst

morphology (i.e., unclear discrimination between serous and mucinous lesions) and growth rate, patient's age, sex, and tumor location. As a matter of fact, most of the patients currently undergoing resections for a serous cystic neoplasm are misdiagnosed with another pancreatic neoplasm, especially in younger individuals with body/tail lesions [13]. In case of a correct diagnosis, surgical resections only play a role for large cysts and with mass effect symptoms. In patients managed operatively, surgical resection ensures cure as serous cystic neoplasms do not recur. Therefore, a postoperative regular radiologic follow-up program is not necessary, thereby saving cost. Follow-up outpatient visits should be therefore focused on quality of life.

Mucinous Cystic Neoplasms

The rate of malignant MCNs found in surgical series is significantly variable, ranging from 0% to >30% and reaching the higher extreme in older studies. Different diagnostic criteria were used over the years, probably causing the inadvertent incorporation of several IPMNs (with a more aggressive behavior) in series which were also including only surgically resected tumors, with a consequent significant selection bias. Conversely, recent data have suggested a lower risk of malignant transformation, especially for smaller tumors [18–20]. In the absence of mural nodules, enhancing walls or cysts <50 mm, the incidence of malignancy may be negligible (and probably not higher than BD-IPMN), favoring surveillance in selected cases given the low risk of malignancy and the high rate of misdiagnosis [21]. As most patients with mucinous cystic neoplasms are middle-aged women with a long-life expectancy, nonoperative management of low-risk lesions based on periodic imaging may require years of radiologic follow-up at high cost. However, the surgical costs are probably higher, the complication rates and mortality are not negligible, and postoperative follow-up is required as well.

Radical resection of noninvasive neoplasms ensures cure. These neoplasms do not recur and, as already pointed out for serous cystic neoplasms, outpatient follow-up should be focused on quality of life. A regular radiologic postresection surveillance can probably be discontinued after five years, depending on final pathology.

Minimally invasive mucinous cystic neoplasms (invasion limited to the ovarian stroma), but without tissue invasion, have an excellent prognosis. On occasion, undocumented foci of invasive carcinoma may exist within a presumably noninvasive proliferative MCN and this emphasizes the importance of a careful histopathologic analysis of the entire lesion. In such cases, recurrence and metastases can be observed. In general, these patients should undergo a radiologic follow-up protocol, despite minimally invasive adenocarcinomas arising in mucinous cystic neoplasms being virtually cured by surgery, particularly if the neoplasms are completely examined histologically [22].

Five-year survival of patients with invasive mucinous cystic neoplasms (true cystadenocarcinoma) appears quite poor, ranging from 15% to 35%, albeit still somewhat better than those for typical ductal adenocarcinoma of the pancreas. The extent of invasion is the most significant prognostic factor in malignant mucinous cystic neoplasms. Some authors have suggested that patients with resected mucinous cystadenocarcinoma should be carefully followed on a six-month basis with cross-sectional imaging, matching the follow-up interval of ductal adenocarcinoma [23]. However, proof that surveillance imaging improves the prognosis compared with a strategy based on symptom recurrence is lacking.

Intraductal Papillary Mucinous Neoplasms

Outcome of IPMN Managed Nonoperatively

Initial follow-up is generally proposed only for patients with BD-IPMN devoid of malignant features (worrisome features and high-risk stigmata according to international guidelines), in which the risk of invasive cancer appears to be low. The majority of evidence confirmed this policy to be safe, with long-term data eventually becoming available.

The decision to follow up a presumed IPMN is based on multiple factors, namely the neoplasm type (main duct/mixed versus branch duct), patient age, family history, symptoms, comorbidities, perceived pancreatic cancer risk, and patient preference [10,11].

A recent observational study focused on IPMNs "crossing over" from observation to surgery, aiming to identify further dynamic predictors of malignant degeneration. In BD-IPMNs under surveillance, the development of additional worrisome features or high-risk stigmata was associated with the presence of high-grade dysplasia, while harboring a stable worrisome feature carried the lowest risk of malignant disease [24].

Subgroups of patients affected by BD-IPMNs with a low risk of malignant degeneration were identified by large observational studies. BD-IPMNs smaller than 1.5 cm without worrisome features were found by Pergolini et al. to have a significantly lower risk of malignant degeneration compared to larger cysts [5]. Marchegiani et al. found that patients older than 65 years of age with a BD-IPMN not developing worrisome

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. features or high-risk stigmata in the first five years of diagnosis have the same risk of malignancy as the age-matched general population [9]. These findings are consistent with data from Lee and colleagues, estimating an invasive cancer incidence of around 1% in patients with BD-IPMNs without significant changes within the first five years of surveillance [25].

However, recently the largest surgical series on IPMNs ever published by a single referral center was presented by the Heidelberg group [26]. In this study comprising around 1439 patients, the "timing" of surgical resection was categorized according to final pathology: too early in case of low-grade dysplasia, too late in case of invasive cancer, and timely in case of intermediate- and high-grade dysplasia. Conversely, radiographic criteria of suspicion were present only in 34% and 88% of the "timely" and "too late" groups, respectively. Therefore, a cautious application of watch-and-wait policies was advocated by the authors.

In general, there is little evidence in the literature to guide the frequency and type of surveillance for IPMN managed nonoperatively. Some authors propose that surveillance can be safely spaced to every two years or even discontinued after long-term stability in low-risk lesions. However, concern over the development of pancreatic ductal adenocarcinoma in the pancreas harboring IPMN prompts continuation of active life-long surveillance at short intervals. Despite a decrease in the presumed overall malignancy risk, it is still too early to recommend discontinuation of surveillance in general based on current evidence, which is still germinal. Undoubtedly, surveillance results in significant utilization of cross-sectional imaging, endoscopic ultrasound, and economic investment. Research is focusing on fluid cyst biomarkers able to discriminate cystic malignant potential.

Outcome after Resection of IPMN

The outcome after resection of IPMN depends on different factors.

- Presence of an invasive component
- Epithelial histologic subtype
- Type of invasive component
- Duct involvement (BD vs MD)
- Resection margin
- Lymph node status (in invasive IPMN)

The prognosis of patients with noninvasive IPMN is excellent, and the five-year survival rate is reported to be >70% in most series. Some series have even suggested a five-year disease-specific survival close to 100% after resection. Conversely, the five-year survival rate for invasive IPMN (carcinoma arising in the background of IPMN) ranges from 34% to 62%. The outcome of invasive IPMN is therefore poor in comparison with noninvasive IPMN, but appears to be better than pancreatic ductal adenocarcinoma, which exhibits a five-year survival ranging from 9% to 21%. Whether this is due to a stage-shift with earlier diagnosis of IPMN, or to a true less aggressive behavior of invasive IPMN remains controversial [27]. Moreover, it has recently emerged that a genetically independent invasive cancer (namely, concomitant) could also arise in the context of an IPMN, making it indistinguishable from an IPMN-derived invasive cancer by classic clinical and pathologic features alone [28]. Disease recurrence may arise either in the pancreatic remnant or in peripancreatic or extrapancreatic sites.

There are data indicating that invasive IPMN is a heterogeneous disease, as it can exhibit different histologic patterns, namely colloid (colloid carcinoma), tubular (tubular adenocarcinoma) or oncocytic (oncocytic carcinoma). According to reports by Furukawa et al. and Mino-Kenudson et al., colloid carcinoma derives from intestinal-type IPMN, and is associated with a particularly indolent behavior [29]. Tubular adenocarcinoma correlates with the gastric and pancreatobiliary epithelial subtypes, and is associated with a dismal prognosis, like that of pancreatic ductal adenocarcinoma. Oncocytic carcinoma derives from the uncommon oncocytic subtype, and has a significantly better outcome than ductal adenocarcinoma, even though it can present with very late tumor recurrence (up to seven years after surgical resection) [27,29,30].

It is well established that the type of duct involvement, branch versus main duct (MD), is associated with the risk of harboring invasive cancer. Because the type of duct involvement correlates with epithelial subtypes of IPMN, it may also identify the likely histologic subtype of cancer. In particular, MD type is mainly intestinal and oncocytic, whereas BD type were often associated with the gastric epithelial type. The association of BD-IPMN/gastric subtype/tubular adenocarcinoma seems paradoxical, because gastric-type BD-IPMNs most often harbor low-grade dysplasia and absence of invasion. In the series by Mino-Kenudson et al., 15.6% of surgically resected gastric-type IPMNs gave rise to tubular adenocarcinoma [27]. According to these findings, the final pathologic report of resected invasive IPMN should indicate the histologic pattern of the invasive component and the background histologic subtype. This is of essential prognostic significance.

The clinical implications of surgical resection margin (frozen section of the pancreatic cut surface) are controversial, and results in the literature are mixed on this topic [31]. In general, not all studies found a strong correlation between margin status and risk of recurrence. There have been reports of invasive carcinomas in association with only mild or moderate dysplasia (adenomas or borderline lesions) within the IPMN in the remnant pancreas. A metaanalysis showed that the recurrence

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

rate in patients with noninvasive IPMN was 3.72% with negative margins and 9.56% with positive margins. The same metaanalysis showed that recurrence after surgical resection of invasive IPMN occurred in 33.8% of patients with negative margins and 53.6% of patients with positive margins [32]. These data are reinforced by a large series from the Massachusetts General Hospital, stating that resection margin is indeed an independent predictor of tumor recurrence for invasive IPMNs [33].

Because recurrence in the remnant may be due to the presence of multifocal disease or to the development of a metachronous IPMN rather than the progression of margin-positive disease, the margin should be used as a marker of residual disease throughout the remnant.

Lymph node status is another factor affecting long-term outcome in invasive IPMN. The five-year survival of patients with positive lymph nodes ranged from 20% to 30%, while N0 patients lived much longer, ranging from 80% to 85%. Lymph node ratio >0.2 has been shown to be associated with worse prognosis [34]. Data from a metaanalysis demonstrated that nearly 77% of lymph node-positive patients recurred, while disease recurrence occurred in only 30.8% of patients with negative lymph nodes [32].

Very little is known about adjuvant chemotherapy for IPMNs, which seemed to improve survival only in invasive IPMNs with nodal disease or tubular differentiation in a recent retrospective series [35]. Evidence is even poorer with respect to neoadjuvant therapies, especially with modern chemotherapy regimens. One of the reasons for this may be the difficulty of achieving a cytologic differential diagnosis between invasive IPMN and pancreatic ductal adenocarcinoma, before the start of chemotherapy. Future trials are urgently needed to improve the level of evidence in this field.

Solid Pseudopapillary Neoplasms

More than 95% of patients with solid pseudopapillary neoplasms limited to the pancreas are cured by complete surgical excision. Local invasion or resectable liver and lymph node metastases are not contraindications for resection, and some patients with advanced tumors can survive for more than 10 years after the operation. During the follow-up period, recurrence of the disease in the liver or lymph nodes is uncommon, at 6.6%. Prognosis for solid pseudopapillary neoplasms with treated liver metastases usually surpasses five years. Conversely, other factors such as the presence of capsular invasion and pancreatic parenchyma invasion seem to correlate with the likelihood of tumor recurrence after complete surgical excision [36]. Overall, two-year survival rate (with or without metastases) was 97%, and five-year survival was around 95%.

Conclusion

The actual natural history of PCNs represents an enigma, which is slowly becoming clearer due to a new era of observational studies with long-term follow-up availability. Because it seems that survival is clearly favorable in comparison with pancreatic ductal adenocarcinoma, it will be of great importance to precisely predict how these neoplasms behave, with respect to the time to degeneration, the risk of developing a new IPMN or additional malignancy, and the risk of disease-specific mortality. The overall major postoperative morbidity and mortality of patients undergoing pancreatic resection for PCNs remain relatively high, similar to those for other indications. For this reason, a tailored and patient-centered decision is mandatory. Accurate surveillance, either pre- and postoperatively, seems necessary in most cystic neoplasms, since most have the potential to become malignant or to recur. On the other hand, the cost of observing thousands of patients is a relevant burden for healthcare systems and being able to select patients amenable for surveillance discontinuation according to different PCNs biology represents an urgent issue.

Introduction

Neuroendocrine tumors (NETs) of the pancreas are a heterogeneous group of epithelial neoplasms with a highly variable clinical presentation, malignant potential, and prognosis. Pancreatic NETs (pNETs) range from small, slow-growing, incidentally detected nonfunctional and/or functional tumors to frank aggressive malignancies. These lesions were earlier described as "islet cell tumors" based on the belief that they originate from cells in the islets of Langerhans. They were later considered to be "pancreatic endocrine tumors" when evidence suggested that they might be originating from pluripotent cells in the ductal epithelium [1,2]. The 2010 World Health Organization (WHO) classification system [3] recommended the use of the term "neuroendocrine" to describe these tumors as they are now considered to arise from cells that are part of the diffuse neuroendocrine cell system of the gastrointestinal tract and pancreas. These cells share certain unique biochemical (ability to synthesize, store, and secrete a number of amines and peptides) and immunohistochemical properties (documentation of markers of neuroendocrine differentiation, mainly expression of antigens commonly expressed by neuronal elements such as chromogranin A and synaptophysin, together with neuron-specific enolase) [4].

Epidemiology of Pancreatic Neuroendocrine Tumors (Table 98.1)

Data on epidemiology of pNETs are limited. Variations in coding and classification over time, and between different countries, have resulted in difficulties in precisely understanding the true epidemiology of these tumors. Moreover, various national, regional, and institutional cancer or NET registries, with their inherent deficiencies in data collection, are the major sources of epidemiology of pNETs.

The pNETs are rare tumors that possibly constitute <3% of all pancreatic tumors [5], and approximately 4–8% of all neuroendocrine tumors [6]. The annual incidence rate of pNETs is reportedly less than 1 per 100 000 person-years in population studies [5]. The absolute annual incidence rate of pNETs varies among registries in various countries, with pNETs ranging from the most common to the second most common site among gastroenteropancreatic NETs. The pNETs are most common between 60 and 80 years of age, with an earlier age of onset in patients with multiple endocrine neoplasia type 1 (MEN 1).

The incidence of pNETs is higher in autopsy studies, ranging from 0.1% to 10% [5]. Grimelius et al. from Sweden reported 13 pancreatic "islet cell adenomas" at autopsy among 1366 adults (0.95%) [7]. Kimura et al. from Japan found 20 "endocrine tumors of the pancreas" among 800 autopsy cases (mean age 78.7 years); the incidence of tumor was higher among the 60 randomly selected cases that had 5 mm thick sections of the pancreas; six (10%) of them were found to have an endocrine tumor as opposed to only 12 out of 738 cases (1.6%) that had histologic studies of three random sections of the pancreas [8]. However, Lam et al. from Hong Kong found only 13 cases (0.1%) of "pancreatic endocrine tumors" among 11472 autopsies performed from 1972 to 1995 [9].

There has been a rise in the incidence and prevalence of pNETs over the past few decades; this could either reflect a true increase in incidence or be the result of increased awareness of these tumors among physicians

Table 98.1 Incidence of pancreatic neuroendocrine tumors in selected autopsy series after 1970s.

First author	Year published	Country	Number of autopsies	Number of "islet cell tumors"	Percentage
Grimelius L	1975	Sweden	1366	13	0.95
Kimura W	1991	Japan	800	20	2.5
Kimura W	1991	Japan	60 (5 mm sections)	6	10
Lam KY	1997	Hong Kong	11472	13	0.1

because of increased recognition and widespread adoption of nomenclature, grading, and staging of these tumors. Moreover, the availability of more sensitive imaging techniques has led to increased detection [10,11]. Using the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database, Dasari et al. in 2017 reported that the age-adjusted annual incidence of all NETs in the USA had increased from 1.09 per 100 000 persons in 1973 to 6.98 per 100 000 persons in 2012, which includes a steep rise in the incidence of pNETs from 0.4 to 0.8 per 100 000 persons from 2000 to 2012 [12]. Another study, which specifically analyzed the annual age-adjusted incidence of pNETs in the USA using the SEER 18 database, reported a sharp increase in incidence of pNETs from 0.2647 to 1.0618 per 100000 persons over the time period 2000-2016 [13]. Similarly, an updated analysis of the epidemiologic trends of NETs in Taiwan reported an increase in incidence from 0.017 in 1996 to 0.446 per 100 000 persons in 2015, an annual percentage change of 28%; the overall percentage of pNETs among 7760 people with NETs increased from 3.65% (1996-2003) to 7.27% (2004-2009) to 13.09% (2010-2015) [14]. Studies based on national databases from China [15], India [16], Japan [17], and Norway [18] have all reported a similar increase in the incidence of pNETs.

Classification of Pancreatic Neuroendocrine Tumors

The classification of pNETs has changed periodically since the first attempts at classification of these tumors were made in the early 60s. They can be classified based upon:

- functionality as "functional or nonfunctional"
- association with inherited syndromes as "sporadic or syndromic"
- tumor biology and morphologic features
- evaluation of spread based on the Tumor-Node-Metastasis (TNM) staging system.

Functional vs Nonfunctional pNETs (Table 98.2)

"Functional" pNETs are associated with a hormone-secreted clinical syndrome. The clinical presentation of these tumors is dominated by the metabolic effects of the excess hormone(s) secreted by the tumor, and they are classified based upon the predominant clinical syndrome produced by the hormone secreted by the tumor. There is a poor correlation between peptide expression on immunohistochemical staining of the tumor and the circulating levels of respective secretory products; thus, the mere presence of positive immunohistochemical staining is not a defining criterion for a "functional" pNET. The updated 2016 European Neuroendocrine Tumor Society (ENETS) consensus guidelines for the management of functional and nonfunctional pNETs divides functional pNETs into "most common functional pNET syndromes," "established rare functional pNET syndromes," and "very rare functional pNET syndromes" [19]. Of the many established and possible functional pNETs, the two that are more commonly seen in clinical practice are insulinomas and gastrinomas.

"Nonfunctional" pNETs do not produce any specific hormone-secreted clinical syndromes. They are either detected incidentally during imaging or present with symptoms attributable to mass effect due to tumor bulk or distant metastases. Although some of them do not produce any amines or peptides, most do secrete substances such as chromogranin, pancreatic polypeptide, neurophysin, neuron-specific enolase, α subunit of human chorionic gonadotropin, and other peptides that do not result in any specific clinical syndrome.

Earlier reports suggested a preponderance of functional pNETs as they presented with recognizable clinical syndromes and were thus easier to identify. However, over the past two decades, nonfunctional pNETs have become the more common pNET as a result of improvement in imaging techniques and increased detection rate [10,11].

The differentiation of pNETs based on functionality does not shed light on their biological behavior or help predict their long-term prognosis in the majority of situations; the one exception is insulinoma, which in the majority of cases runs an indolent course. As such,

Table 98.2 Functional pancreatic neuroendocrine tumors.

	Endocrine hormone secreted	Approximate incidence Patients per million per yr	Likelihood of malignancy (%)
More common			
Insulinoma	Insulin	2	<10
Gastrinoma	Gastrin	1	>50
Less common			
Glucagonoma	Glucagon	0.05 or more	>50
VIPoma	Vasoactive intestinal peptide	0.05	>50
Somatostatinoma	Somatostatin	Rare	>50
ACTHoma	Adrenocorticotrophic hormone	Rare	>50
GRFoma	Growth hormone-releasing hormone	Rare	>50
"Classic" carcinoid syndrome	Serotonin	Rare	>50
PTHrp-oma	Parathyroid hormone-related peptide	Rare	>50
Rare			
Calcitonin-omas	Calcitonin	Very rare	>50
Others (may be mixed)			
Hormones	"Big IGF-II", erythropoietin, luteinizing hormone, renin, CCK, GLP-1	Very rare	Unknown

the biological behavior of functional pNETs should also be classified as one would classify a nonfunctional pNET, including the grade and stage of the tumor. However, it is essential to identify functional pNETs because they produce classic hormone-secreted clinical syndromes that require dedicated investigations, therapeutic interventions, and structured long-term follow-up.

Sporadic vs Syndromic pNETs (Table 98.3)

Less than 10% of pNETs are associated with inherited disorders. The four common inherited disorders that manifest a pNET are multiple endocrine neoplasia type 1 (MEN 1), von Hippel–Lindau disease (VHL), neurofibromatosis type 1 (von Recklinghausen disease) (NF 1), and tuberous sclerosis complex (TSC) [20].

Approximately 80–100% of patients with MEN 1, 10–17% of patients with VHL, up to 10% of patients with NF 1, and 1% of patients with TSC will develop a pNET within their lifetime [20]. The pNETs associated with inherited disorders are frequently multifocal. As with functional pNETs, the association of these tumors with a specific inherited syndrome does not help predict their biological behavior or long-term prognosis. However, it is important to recognize a syndromic pNET not only to prompt a diligent search in the index patient to identify the multifocal pancreatic and extrapancreatic tumors but also to allow early and periodic surveillance of family members.

Table 98.3 Pancreatic neuroendocrine tumors associated with hereditary syndromes.

Syndrome	Gene location	Incidence %	Tumor type	Location
MEN 1	11q13	80–100	Nonfunctional, gastrinoma, insulinoma	Pancreas Duodenum
VHL disease	3p25	10-17	Nonfunctional	Pancreas
NF 1	17q11	Up to 10	Somatostatinoma	Pancreas
TSC	9q34 (TSC 1) 16p13.3 (TSC 2)	<5	–	Pancreas

MEN, multiple endocrine neoplasia; NF, neurofibromatosis; TSC, tuberous sclerosis complex; VHL, von Hippel–Lindau.

Based on Tumor Biology and Morphologic Features (Tables 98.4–98.6)

Over the years, the classification of this rare group of tumors has evolved, and a number of earlier classification systems exist. Most classification systems do make a clear and sharp distinction between well-differentiated pNETs and poorly differentiated pancreatic neuroendocrine carcinomas (pNECs) that have an aggressive course with poor prognosis. Morphologic features of the tumor, extent of local/distant spread, and aggressiveness of the tumor are common to most classification systems. It should be emphasized that almost all pNETs are potentially malignant, and can metastasize, even after many years.

The salient classification systems proposed over the years for pNETs include the following.

- Capella classification system 1995 [21]
- Armed Forces Institute of Pathology (AFIP) classification system 1997 [22]
- Memorial Sloan Kettering classification system 2002 [23]
- 2004 WHO classification system [24]
- 2006 ENETS TNM staging and grading system [25]
- 2010 WHO classification system [3]
- International Union for Cancer Control/American Joint Committee on Cancer/WHO TNM staging system 2010 [26,27]
- 2017 WHO classification system [28]
- Eighth edition of the AJCC/UICC TNM staging system (2018) [29]

Table 98.4 2006 European Neuroendocrine Tumor Society grading proposal for pancreatic neuroendocrine tumors.

Grade	Mitotic count per 10 high-power fields[a]	Ki-67 labeling index (%)[b]
Grade 1 (G1)	<2	≤2
Grade 2 (G2)	2–20	3–20
Grade 3 (G3)	>20	>20

[a] 10 high-power fields = 2 mm^2, at least 40 fields (at 40× magnification; evaluated in areas of highest mitotic density).
[b] MIB1 antibody; percentage of 2000 tumor cells in areas of highest nuclear labeling.

Table 98.5 2017 World Health Organization classification and grading of pancreatic neuroendocrine tumors.

Classification/grade	Mitotic count (per 10 high-power fields)	Ki-67 labeling index (%)
Well-differentiated pNETs		
Neuroendocrine tumour – Grade 1	<2	<3
Neuroendocrine tumour – Grade 2	2–20	3–20
Neuroendocrine tumour – Grade 3	>20	>20
Poorly differentiated pNETs		
Neuroendocrine carcinoma – Grade 3 (Small cell type) (Large cell type)	>20	>20
MiNEN (Mixed endocrine nonendocrine neoplasm)		

Table 98.6 Comparison of the 2010 and 2017 World Health Organization classification and grading of pancreatic neuroendocrine tumors.

WHO 2010 classification/grade	WHO 2017 classification/grade	Mitotic count (per 10 high-power fields)	Ki-67 labeling index (%)
Well-differentiated pNETs

We will restrict ourselves in this chapter to describing in detail the 2004, 2010, and 2017 WHO pNETs classification systems [3,24,28], the ENETS TNM staging and grading system proposed in 2006 [25], and the seventh (2009/2010) and eighth editions (2018) of the AJCC/UICC TNM staging systems [26,27,29].

2004 WHO Classification of pNETs

The 2004 WHO classification system divided pNETs into well-differentiated endocrine tumors with benign behavior, well-differentiated endocrine tumors with uncertain behavior, well-differentiated endocrine carcinomas (WDEC), poorly differentiated endocrine carcinomas (PDEC), and mixed exocrine and endocrine tumors [24]. Unlike the earlier 1995 Capella classification system [21], apart from staging parameters (such as tumor size, invasion of adjacent structures, and metastases), grading parameters (such as the aggressiveness of the tumors, as assessed by the mitotic activity and/or Ki-67 labeling index) were introduced to refine prognostication. Unlike the earlier 2002 Memorial Sloan Kettering classification system [23], which included presence of necrosis for grading, the 2004 WHO classification was based solely on the proliferative rate of the tumor as reflected by the mitotic activity and/or Ki-67 labeling index for grading. This classification was tested clinically and found to have prognostic relevance [30].

The 2004 WHO classification system was a hybrid of staging and grading; an attempt at classification of pNETs was made based not only on staging parameters but also on the grade of tumor. However, tumor stage and grade have independent prognostic significance. Moreover, the 2004 WHO classification system did not allow for the application of the system to advanced stages of the disease; an advanced pNET need not necessarily be very aggressive; this is evident especially in metastatic pNETs wherein, depending upon tumor grade, some metastatic disease remains indolent for prolonged periods of time whereas others progress rapidly.

2006 ENETS TNM System (Tables 98.4 and 98.7)

In 2006, the ENETS proposed a TNM staging system of foregut NETs (including pNETs), which also included a grading system [25]. The 2006 ENETS grading and TNM staging system effectively separated staging from grading. It was realized that unlike poorly differentiated endocrine carcinomas (PDECs), where the behavior of the tumor is more aggressive and predictable, it was difficult to predict the behavior of well-differentiated pNETs, which could range from being indolent to the more aggressive forms. It was therefore decided to subdivide well-differentiated pNETs into two grades to help prognosticate them better based on proliferation markers of mitoses and Ki-67 labeling index. They proposed that mitoses should be counted in at least 40 high-power fields (HPFs) in areas where they are most frequent, and expressed as number of mitoses per 10 HPFs (2 mm^2). Only clear-cut mitotic figures should be counted. For Ki-67 protein assessment, they recommended that the labeling index should be assessed in 2000 tumor cells in areas where the highest nuclear labeling is observed. Ki-67 is a nuclear protein expressed in dividing cells closely associated with the nucleolus and heterochromatin. The monoclonal MIB-1 antibody is used for labeling.

Pancreatic NETs were divided into three tumor categories: grade 1 (G1), grade 2 (G2), and grade 3 (G3), based on the number of mitoses seen per 10 HPFs and/or the percentage of tumor cells that stain for Ki-67. In general, G1 and G2 referred to well-differentiated pNETs, and G3 indicated poorly differentiated neuroendocrine carcinoma.

Table 98.7 2006 ENETS TNM classification and disease staging system for endocrine tumors of the pancreas.

T definition	Primary tumor
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Limited to the pancreas and size <2 cm
T2	Limited to the pancreas and size 2–4 cm
T3	Limited to the pancreas and size >4 cm or invading duodenum or bile duct
T4	Invading adjacent organs (stomach, spleen, colon, adrenal gland) or the wall of large vessels (celiac axis or superior mesenteric artery)
	For any T, add (m) for multiple tumours
N definition	**Regional lymph nodes**
Nx	Regional lymph node cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
M definition	**Distant metastases**
Mx	Distant metastasis cannot be assessed
M0	No distant metastases
M1	Distant metastasis
Stage definition	
Stage 1	T1, N0, M0
Stage IIa	T2, N0, M0
Stage IIb	T3, N0, M0
Stage IIIa	T4, N0, M0
Stage IIIb	Any T, N1, M0
Stage IV	Any T, any N, M1

2010 WHO classification system (Table 98.6)

The aim of the 2010 WHO classification system was to further standardize the classification of gastroenteropancreatic (GEP)-NETs [3]. It used a proliferation-based grading system together with the classic histologic features-based classification. It emphasized the malignant potential of pNETs.

It divided pNETs into "neuroendocrine tumours" (NETs), which include low-to-intermediate grade, well-to-moderately differentiated pNETs, and "neuroendocrine carcinomas" (NECs), which include high-grade, moderately-to-poorly differentiated pNETs. The 2010 WHO classification endorsed the ENETS 2006 TNM staging and grading system [25]; based on the proliferative rate of the tumor (mitotic count/10 HPF and/or Ki-67 labeling index), pNETs were divided into three grades: grade 1 (G1) and grade 2 (G2) tumors referred to NETs, whereas NECs were all uniformly high-grade tumors (G3). In cases of discordance between mitotic count and Ki-67 labeling index in assessing proliferation rate, the 2010 WHO classification system recommended use of the higher grade of either mean.

Unlike the 2004 classification system [24], the 2010 WHO classification system separated grading from staging. Classification is primarily based upon the proliferative rate of the tumor rather than stage-pertinent features such as size of tumor, regional invasion or distant metastases. The 2010 classification system recognized the need for a separate staging system, and together with the AJCC, endorsed the TNM staging system developed in 2009 by the UICC (UICC/AJCC/WHO 2010 TNM) [26,27]. This separation of grading from staging, which was earlier proposed by the ENETS in 2006, allowed for prognostication of pNETs even when insufficient information is available for staging, a fairly frequent scenario in clinical practice, when only small biopsy specimens are available for assessment of tumor grade but detailed clinical assessment, including size and invasion, is missing.

However, it was soon realized that there was a discrepancy between grading and differentiation in the grade 3 pancreatic neuroendocrine carcinoma (pNEC) group as classified in the 2010 WHO system; a few morphologically well-differentiated pNETs with a high Ki-67 labeling index were technically classified as grade 3 NEC [31]. However, these well-differentiated NETs, classified as grade 3 NEC, have a better prognosis than, and are generally not as sensitive to the chemotherapy regimen used for, poorly differentiated grade 3 NEC. Thus, the definition of grade 3 NEC based solely on mitotic index and/or Ki-67 labeling index was too broad, and failed to distinguish between grade 3 NET and grade 3 NEC, leading to inappropriate treatment decisions and unsatisfactory clinical outcomes.

2017 WHO Classification System (Tables 98.5 and 98.6)

To correct the above discrepancy, the latest 2017 WHO classification system has not only taken cellular proliferation but also cellular differentiation into consideration, and has thus changed the definition of grade 3 NEC [28]. Grade 3 NEC has now been divided into two groups: a new subset of grade 3 pNETs has been introduced, which includes morphologically well-differentiated pNETs with high mitotic index and/or Ki-67 labeling index (>20%), and the earlier grade 3 pNEC now includes only the morphologically poorly differentiated pancreatic neuroendocrine carcinoma with high mitotic index and/or Ki-67 labeling index (>20%) [28]. The 2017 WHO classification system retains the earlier pNETs grade 1 and grade 2 categories. It has also changed the nomenclature for mixed adenoneuroendocrine carcinoma (MANEC), as described in the 2010 classification system, to mixed endocrine nonendocrine neoplasm (MiNEN). This change has been made to acknowledge the fact that not all mixed tumors are high-grade malignant carcinomas; moreover, the nonendocrine component may include carcinomas other than adenocarcinoma, including acinar cell carcinoma or squamous cell carcinoma. Table 98.6 lists the differences between the 2010 and 2017 WHO classification systems for pNETs.

Tumor-Node-Metastasis (TNM) Staging System
(Tables 98.7, 98.8 and 98.9)

The TNM staging system is an instrument for prognostication, allowing death risk assessment at diagnosis and guiding therapy. The ability to stratify patients into different stages at diagnosis reflecting increasingly worsening prognosis allows for planning of progressively more aggressive therapy. The success of the TNM staging system depends to a large extent on its ability to reflect the biology and natural history of the cancer. Well-differentiated pNETs, which are much more common than the more aggressive poorly differentiated pNETs, are biologically different from adenocarcinoma of the pancreas; they are larger in size, more indolent, late to metastasize, run a long course despite widespread metastases, and overall have a much better prognosis than adenocarcinoma of the pancreas.

A TNM staging system for pNETs was first proposed in 2006 by the ENETS [25]. Subsequently, in 2009, the UICC released the seventh edition of the TNM classification of malignant tumors, which included a TNM staging system for well-differentiated pNETs [26]; this staging system was subsequently endorsed by both the AJCC and the WHO in 2010 [27]. However, tumor definition and the derived stages differed slightly between the two staging systems; as a result, although both systems used identical TNM terminology, they referred to

Table 98.8 TNM classification and disease staging for well-differentiated endocrine tumors of the pancreas (eighth edition of the AJCC/UICC 2018)

Definitions	UICC/AJCC/WHO 2010 TNM
T definition	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Limited to the pancreas and <2 cm in greatest dimension
T2	Limited to the pancreas and 2–4 cm in greatest dimension
T3	Limited to the pancreas, >4 cm or invading the duodenum or common bile duct
T4	Tumor invades adjacent structures
N definition	**Regional lymph nodes**
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
M definition	**Distant metastasis**
M0	No distant metastasis
M1 M1a M1b M1c	Distant metastasis Metastasis confined to liver Metastasis in at least one extrahepatic site Both hepatic and extrahepatic metastasis
Stage definition	
Stage I	T1, N0, M0
Stage II	T2–T3, N0, M0
Stage III	T4, N0, M0 Any T, N1, M0
Stage IV	Any T, any N, M1

slightly different extent of disease. The major source of contention was the tumor stage T3: the 2010 UICC/AJCC/WHO TNM staging system defined it as peripancreatic tumor spread without major vascular invasion whereas the 2006 ENETS system defined it as tumor 4 cm in size, confined to the pancreas, or invading the duodenum or bile duct.

The 2006 ENETS TNM staging system has subsequently been validated by a number of series reporting on pNETs [32–35]. Since its introduction in 2006, it has been widely used in Europe, with good prognostic discriminatory power amongst the various stages of pNETs. In contrast, although a number of centers in the United States were mandated to use the 2010 UICC/AJCC/WHO TNM staging system, independent validation of this system is limited [36]. Rather, there was a significant overlap of survival between stages II and III when using the 2010 UICC/AJCC/WHO TNM staging system.

Overall, both these TNM staging systems are predictive of patient outcome, and when combined with classification based on histologic and proliferative features, help stratify pNETs into groups of increasing malignant potential. However, a comparison between the 2006 ENETS and the 2010 UICC/AJCC/WHO TNM staging systems, analyzing 891 patients from eight European centers, found the 2006 ENETS TNM staging system to be superior and more accurate than the 2010 UICC/AJCC/WHO TNM staging system [34].

The limitations and inconsistencies in the seventh edition of the AJCC/UICC 2009/2010 staging system led to the introduction of the eighth edition in 2018 for well-differentiated pNETs [29]. Just as in the seventh edition, pancreatic neuroendocrine carcinomas continue to be staged similar to pancreatic ductal adenocarcinoma. The criterion for peripancreatic tumor spread of well-differentiated pNETs to define T3 in the seventh edition has been removed in the eighth edition; rather, as with the ENETS staging system for well-differentiated pNETs, tumor staging is mainly based on size. The M1 category has been further subdivided in the eighth edition into three stages depending upon the metastatic sites.

However, despite these changes, there still remains discrepancy in the derived stages between the 2006 ENETS staging system and the 2018 AJCC/UICC staging system. The 2006 ENETS system subdivides stage II and III into IIA/IIB and IIIA/IIIB whereas the 2018 AJCC system classifies well-differentiated pNETs into four simple stages, without dividing any of the stages into subcategories (Table 98.9).

The eighth edition of the AJCC/UICC staging system for pNETs has been validated recently; it was found to provide better discrimination in overall survival rate and disease-free survival rate than the 2006 ENETS and the seventh edition of AJC/UICCC staging systems [37].

Further modifications of the TNM staging system of pNETs are to be expected in the future. However, such modifications should be undertaken only after carefully analyzing the ability of the two existing systems, namely the 2006 ENETS and the 2018 AJCC/UICC TNM staging systems, in prognosticating pNETs, which should be assessed by collecting data using uniform protocols in a prospective manner. Until the adoption of such a unified TNM staging system, one should clearly mention which of the two systems has been used for TNM staging to allow for comparison between reported series using the alternate TNM staging system.

The current staging system for poorly differentiated pancreatic neuroendocrine carcinomas is unsatisfactory. pNECs account for approximately 15% of all pancreatic neuroendocrine tumors [38,39]. The vast majority of participants studied to design the 2006 ENETS TNM staging system had well-differentiated pNETs, and

participants with pNECs were underrepresented. The 2010 UICC/AJCC/WHO system and the updated eighth edition of the AJCC/UICC TNM staging system recommended using the same staging system for pNECs as used for exocrine pancreatic malignancies. The tumor definitions and derived stages for pNECs from the 2006 ENETS and the seventh and eighth editions of UICC/AJCC TNM staging systems differ [40].

The major difficulty in designing a pNEC-specific TNM staging system stems from the fact that because of its rarity, most studies on pancreatic neuroendocrine tumors have included very few participants with pNECs. A recent study that included 644 participants with pathologically confirmed pNECs from the SEER database found that the seventh edition of the AJCC/UICC TNM staging system was superior to the eighth edition and the 2006 ENETS staging systems for predicting the prognosis of pNECs [40]. However, the study authors suggested minor modifications in the seventh edition of the UICC/AJCC TNM staging system to allow for more accurate and reliable prediction of pNEC prognosis.

As with the staging of pNETs, further modifications of the TNM staging system of pNECs is to be expected in the future. Until the adoption of such a unified TNM staging system for pNECs, one should clearly mention

which system has been used for the TNM staging to allow comparison between reported series using the alternate TNM staging system.

Conclusion

Pancreatic NETs should be classified based on the 2017 WHO classification system into morphologically well-differentiated NET (grade 1, 2 or 3) or morphologically poorly differentiated NEC (grade 3). Grading should be assessed using both the number of mitoses per 10 HPFs and the Ki-67 labeling index; however, if the specimen size is small, such as a biopsy specimen, with insufficient HPFs for mitoses examination, then grading can be based solely on the Ki-67 labeling index. In the rare event of discordance between the two markers of proliferation rate, use the higher grade. Pancreatic NETs should also be staged, whenever possible, using one of the two current TNM staging systems (2006 ENETS or 2018 AJCC/UICCTNM). Care should be taken to mention the TNM staging system used. The 2017 WHO 2010 classification and a TNM staging system should be applied to all pNETs irrespective of whether they are functional or nonfunctional, syndromic or sporadic.

Further refinements in the classification and TNM staging systems of pNETs can be expected to allow for better prognostication and death risk assessment at diagnosis, and to guide therapy. Collection of prospective data from multiple centers using unified management protocols over the coming years is the key for future refinement of the classification system of well-differentiated pNETs, and hopefully the emergence of a unified TNM staging system. Moreover, the current system for staging poorly differentiated pNECs is rather unsatisfactory and further modifications of the TNM staging system of pNECs is to be expected in the future. However, until that time, the 2017 WHO 2010 classification system, together with the use of either one of the two TNM staging systems (2006 ENETS or 2018 AJCC/UICC), should remove much of the earlier controversy surrounding the classification of these rare endocrine tumors of the pancreas, allowing proper prognostic stratification, guiding appropriate stage- and grade-specific therapy, enabling evaluation of new therapies and comparison of results of published therapeutic trials on pNETs.

Definition, Terminology, and Classification of PanNEN

Pancreatic neuroendocrine neoplasms (PanNENs) are malignant epithelial neoplasms with neuroendocrine differentiation. Based on the current World Health Organization (WHO) classification published in 2019 for digestive organs and in 2022 for endocrine pancreas, PanNENs are divided into neuroendocrine tumors (NETs), neuroendocrine carcinomas (NECs), and mixed nonneuroendocrine and neuroendocrine neoplasms (MiNENs) [1,2]. The same classification system and terminologies are applied to NENs in other digestive organs [1].

A NET is a well-differentiated NEN and is classified into NET G1, G2, and G3 based on one of the higher values of Ki-67 proliferation index (%) and mitotic counts in 2 mm^2 (Table 99.1).

The grading of pancreatic NETs (PanNETs) is significantly associated with patient outcome [3]. The Ki-67 proliferation index is a percentage of nuclear labeling of tumor cells counted in at least 500 tumor cells. Mitotic counts are number of mitotic figures evaluated in 2 mm^2 of the tumor area. The Ki-67 proliferation index is distinctly higher than mitotic counts in most cases and predicts patient survival in PanNETs [4,5]. NET G3 was first proposed in the WHO classification for endocrine pancreas and has been applied for all digestive systems in the 2019 WHO classification [1,2]. PanNET G3 accounts for 2% of primary PanNETs [3] and 15% of primary and metastatic PanNETs [6]. Pancreas is the most frequent origin for NET G3 among digestive organs [6]. The relevant tumors have also been recognized in nondigestive organs including lung and thymus [6–8].

PanNETs smaller than 5 mm are termed pancreatic neuroendocrine microtumors. Microadenomatosis is a multifocal occurrence of microtumors.

PanNETs can be associated with clinical syndromes (functioning/syndromic PanNETs) caused by abnormal hormone secretion by tumor cells. These include mainly insulinomas, gastrinomas, glucagonomas, VIPoma and other rare hormone-secreting PanNETs, such as ACTH and serotonin.

Functioning PanNETs account for less than 40% of all PanNETs [9]. Nonfunctioning PanNETs are not associated with clinical symptoms by abnormal peptide hormone secretion. Nonfunctioning PanNETs are often diagnosed incidentally; 30–70% of patients with multiple endocrine neoplasia type 1 (MEN 1), caused by a germline mutation of a tumor suppressor gene *MEN1* located on chromosome 11q13, develop PanNETs [2]. MEN 1-associated PanNETs are typically multiple microtumors (microadenomatosis) and macrotumors (NETs), of which often one functioning PanNET (i.e., insulinoma) is present [10]. In addition, patients typically develop small duodenal gastrinomas that lead to Zollinger–Ellison syndrome [10]. About 12% of patients with von Hippel–Lindau syndrome (VHL), caused by a germline mutation of the *VHL* tumor suppressor gene on chromosome 3q25, develop PanNETs and the VHL-associated PanNETs are so far all nonfunctioning [11]. PanNETs may arise in 3–9% of patients with tuberous sclerosis [12,13]. Tuberous sclerosis (TSC) is an autosomal dominant disorder caused by a germline mutation of the tumor suppressor gene *TSC1* or *TSC2*. The TSC-associated PanNET can be both functioning and nonfunctioning sclerosis [12,13]. Neurofibromatosis 1 (NF1), caused by a germline mutation of *NF1*, may be associated with somatostatin-producing periampullary NETs.

Table 99.1 World Health Organization 2022 classification of neuroendocrine neoplasms of the digestive system.

	Mitotic index (per 2mm^2)	Ki-67 index (%)
Well differentiated NENs		
NET G1	<2	<3
NET G2	2–20	3–20
NET G3	>20	>20
Poorly differentiated NENs		
NEC	>20	>20

Pancreatic NECs (PanNECs) are classified into large cell and small cell types based on cellular morphology and both types are aggressive neoplasms. PanNECs have a common molecular genetic background as pancreatic ductal adenocarcinomas and are distinct from those of PanNETs (see Chapter 100 Molecular genetics of neuroendocrine tumors) [14,15].

Pancreatic MiNENs are composed of both NEN and non-NEN, each component constituting more than 30% of the total tumor tissue. Most pancreatic MiNENs are mixed ductal neuroendocrine carcinomas.

In the TNM classification system created by the Union for International Cancer Control (UICC), PanNETs and PanNECs are treated separately but the differences are limited, only seen in pT1, pN1, and pM1 categories (Table 99.2) [16].

Macroscopy

PanNETs can arise in all parts of the pancreas. Smaller PanNETs are usually well circumscribed, showing a monotonous colored, whitish tan to yellowish cut surface (Fig. 99.1a). Larger PanNETs often show a multinodular

Table 99.2 TNM classification of pancreatic neuroendocrine tumors proposed by the European Neuroendocrine Tumor Society (ENETS TNM) and by the International Union for Cancer Control/American Joint Cancer Committee/WHO in 2017 (UICC/AJCC TNM, 8th edition). Source: [16]/John Wiley & Sons.

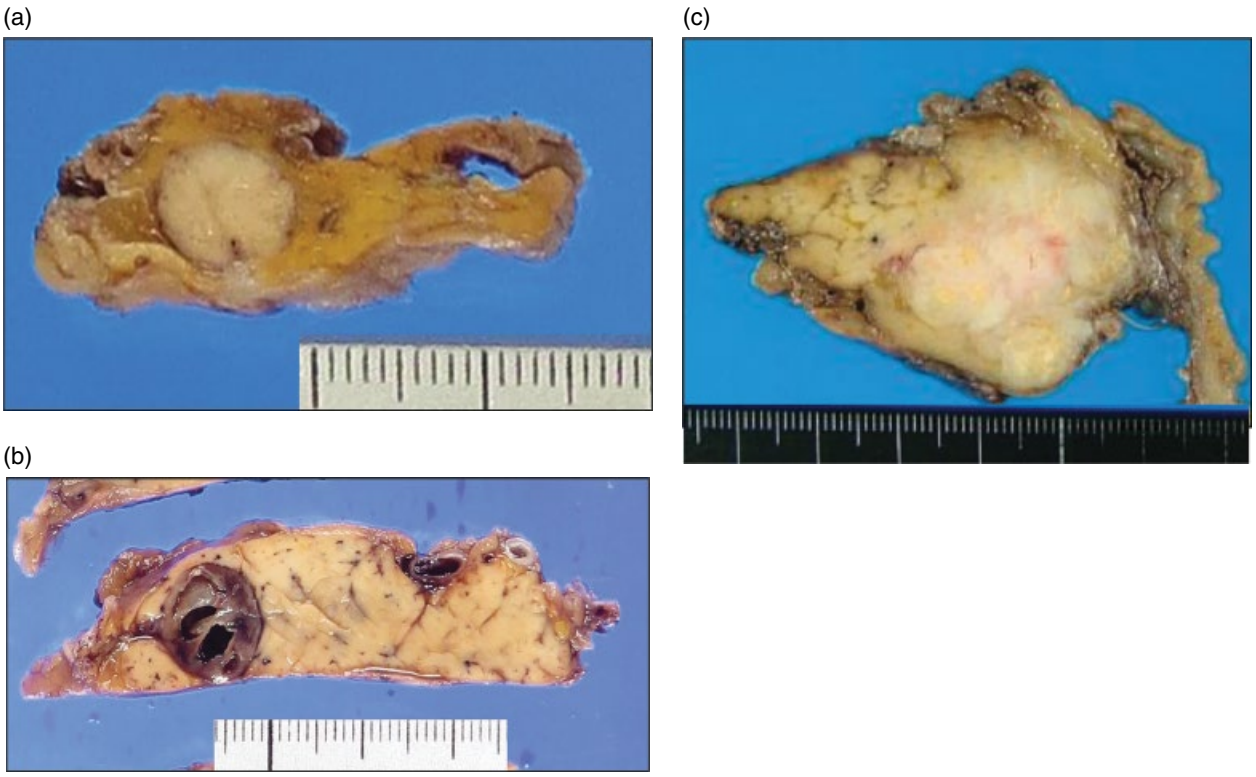

Figure 99.1 Macroscopic images of pancreatic neuroendocrine neoplasms (PanNENs). (a) A round to oval-shaped, well-circumscribed tumor with a whitish-tan cut surface observed in pancreatic neuroendocrine tumor (PanNET) G1. (b) A well-demarcated tumor with cystic changes observed in PanNET G1. (c) A tan-white and focally yellowish tumor with unclear boundaries observed in pancreatic neuroendocrine carcinoma (PanNEC) large cell type.

and heterogenous cut surface. Tumor size at the time of surgery varies from 0.5 cm to 20 cm in diameter. Insulinomas are generally detected as small lesions (<2 cm), whereas nonfunctioning PanNETs are usually detected as larger lesions. Cystic degeneration is not rare and is often associated with glucagon production by the tumor cells (Fig. 99.1b) [17]. PanNECs exhibit unclear boundaries (Fig. 99.1c). Necroses are not uncommon in NETs G3 and NECs (Fig. 99.1c).

Microscopy

PanNETs are characterized by solid and trabecular growth patterns. Solid tumor cells show either a solid-nested or paraganglioma-like pattern. The trabecular growth patterns include trabecular NOS, trabecular-reticulated (Fig. 99.2a,b), trabecular-gyriform and trabecular-glandular patterns (Fig. 99.2c). Capillary or fibrocapillary stroma intervenes within tumor cell nests (Fig. 99.2a). Tumor cells of PanNETs are uniform in size and shape, having round to oval nuclei, with a coarsely granular (so-called salt and pepper) chromatin pattern (Fig. 99.2a). Nucleoli may be observed but are mostly inconspicuous (Fig. 99.2a). Cytoplasm of the tumor cells is mostly granular and appears to be slightly eosinophilic. The extent of fibrosis or hyalinosis varies among cases. Stromal amyloid deposition is occasionally observed in functioning PanNETs, especially insulinoma (Fig. 99.2e).

Oncocytic PanNETs exhibit abundant eosinophilic cytoplasm due to abnormal mitochondrial accumulation. Oncocytic PanNETs tend to display larger nuclei and conspicuous nucleoli (Fig. 99.2f) and tend to have a higher incidence of lymph node metastasis [18]. Clear cell PanNETs have abundant clear cytoplasmic vacuoles or foamy microvesicular cytoplasm (Fig. 99.2g). Nuclei are pushed by lipid vacuoles and appear to be polygonal and pyknotic. Clear cell features have been described in VHL-associated PanNETs [19,20]. Pleomorphic PanNETs present large and hyperchromatic nuclei with marked pleomorphism, without high proliferative activity or necrosis (Fig. 99.2h) [21]. Hepatoid PanNETs are characterized by polygonal cells, prominent nucleoli, and pale acidophilic cytoplasm [21].

PanNECs are characterized by diffuse or solid sheet-like patterns with geographical necrosis. Tumor cells of the large cell type have a high degree of nuclear pleomorphism,

nuclear enlargement, and high nuclear–cytoplasmic ratio. Necrosis is abundant in most cases. Small cell NECs are characterized by a diffuse growth of cells with scant or elongated nuclei, finely granular chromatin, and inconspicuous nucleoli (Fig. 99.3a). The tumor cells are polygonal or uniform round with rich cytoplasm and large nuclei with prominent nucleoli (Fig. 99.3b). Ki-67 proliferation index of NECs mostly exceeds 50%.

Most MiNENs arising in the pancreas consist of two components: either ductal adenocarcinoma or acinar cell carcinoma and neuroendocrine carcinoma. The different components are either intimately intermingled or morphologically distinguishable. In rare cases, the neuroendocrine components show a well-differentiated morphology of the corresponding NET.

Cytology

Due to development of endoscopic ultrasound-guided fine needle aspiration, cytology assessment has become a standard pathologic diagnostic tool for PanNET. Nuclei of tumor cells display a monotonous appearance; they are uniformly round to oval shaped, with a salt and pepper chromatin pattern or, often, plasmacytoid epithelial cells (Fig. 99.4a,b). Tumor cells of PanNETs show loosely cohesive clusters. Single cells are also frequently observed (Fig. 99.4a). Tumor cells surrounding and loosely attached to capillary vessels are frequently observed (Fig. 99.4b). A rosette-like arrangement is highly specific to PanNETs, but rarely seen in cytology specimens.

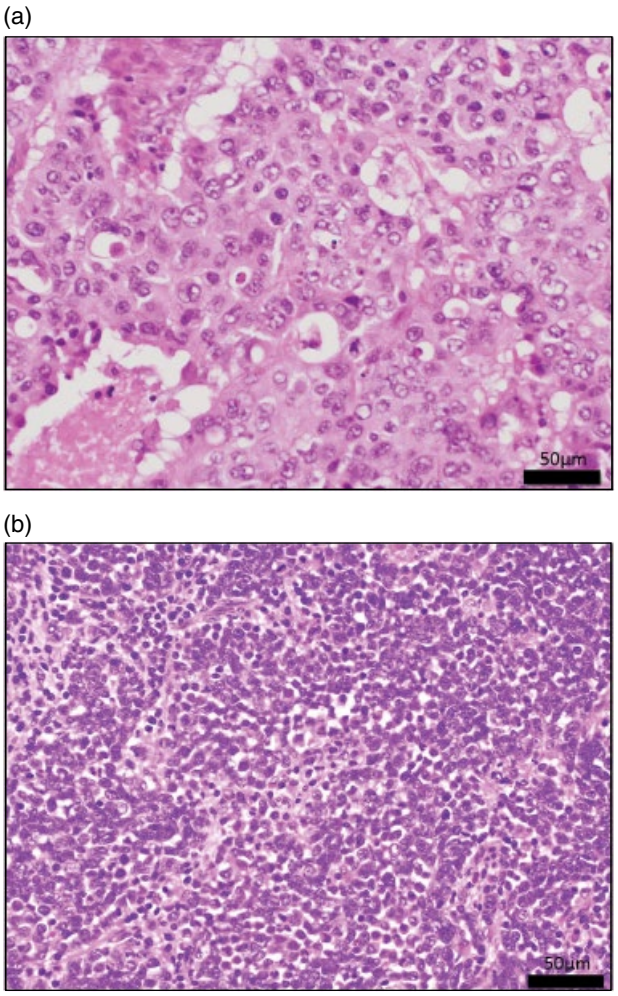

Figure 99.3 Microscopic features of pancreatic neuroendocrine carcinoma (PanNEC). (a) Large cell NEC displaying highly pleomorphic tumor cells showing diffuse growth pattern. Necrosis is also observed. (b) Small cell NEC composed of small round tumor cells with high nuclear-cytoplasmic ratio.

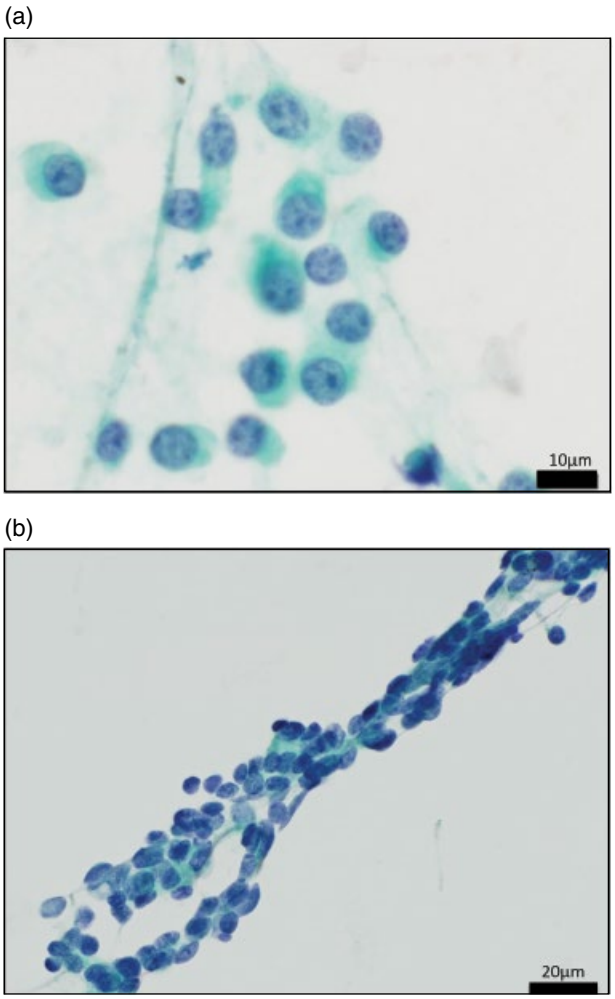

Figure 99.4 Cytology images of pancreatic neuroendocrine tumors (PanNET). (a) Loosely cohesive plasmacytoid epithelial cells with round to oval-shaped nuclei showing "salt and pepper" chromatin pattern. (b) Tumor cells surrounding capillary vessels.

Immunohistochemistry

PanNETs diffusely and strongly express cytokeratin, chromogranin A, and synaptophysin. The other neuroendocrine markers, such as CD56 and neuron-specific enolase (NSE), are not specific. Nuclear expression of insulinoma-associated 1 (ISNM1) is a new neuroendocrine marker and is consistently positive in PanNETs [22].

In PanNECs, extent of cytokeratin and chromogranin A expression is variable, sometimes showing only focal and dot-like positivity. Normal expression of p53 and retinoblastoma 1 (Rb1) is highly suggestive for NETs, while abnormal expression of p53 and loss of Rb1 is suggestive for NEC [6,15]. Membranous expression of somatostatin receptor 2A (SST2) is expressed in more than 70% of PanNETs, but less than 10% of PanNECs, so is a powerful marker in distinguishing NETs from NECs [15,23,24].

ISLET-1, a transcription factor, is expressed in more than 90% of PanNETs and therefore, together with pancreatic peptide hormones (e.g., glucagon, PP), is a helpful marker to separate from NETs originated from other organs [25]. CDX2 is usually expressed in intestinal NETs but may also be expressed in about 50% of PanNETs [26]. Peptide hormone expressions are occasionally associated with certain morphologic patterns in PanNETs [17]. PanNETs with a trabecular-reticulated pattern often show a cystic growth and express glucagon. PanNETs with a solid paraganglioma-like pattern and with psammoma bodies often contain somatostatin-positive cells [27]. PanNETs that express serotonin often show a sclerotic stromal change and a solid-trabecular growth pattern [10].

Differential Diagnosis

PanNETs and PanNECs show distinct morphology in most cases but some PanNETs G3 may morphologically resemble large cell PanNECs and overlap Ki-67 proliferation index. Immunohistochemistry of normal expression of p53 and Rb1 and membranous expression of SST2 (see above), as well as loss of DAXX and ATRX expression, are suggestive for PanNETs and helpful to differentiate from PanNEC [15,28].

PanNETs showing a paraganglion-like pattern are morphologically like paraganglioma occurring in peripancreatic tissue. Paragangliomas show a strong and diffuse expression of neuroendocrine markers but are consistently negative for cytokeratin and positive for GATA3 and differ from PanNETs. S-100-positive sustentacular cells are characteristic in paraganglioma but may occasionally be seen in PanNETs [27].

Solid-pseudopapillary neoplasms (SPN) show low-grade cellular atypia and may resemble PanNETs. SPNs have characteristic pseudopapillary architectures, PAS-positive globules, hyalinosis, cystic degeneration, myxoid degeneration or solid and large calcification. Nuclear expression of β-catenin and somatic *CTNNB1* mutation are diagnostic features of SPN. In PanNETs β-catenin is expressed in cell membrane. Synaptophysin and cytokeratin 8/18 expression are not uncommon in SPN, but chromogranin A is consistently negative [29,30].

The architectural pattern of acinar cell carcinomas is variable, such as acinar, solid, trabecular, and diffuse, and these patterns are usually intermingled. Tumor cells have hyperchromatic nuclei, eosinophilic granular cytoplasm. PanNETs, especially NET G3, with a solid or solid-trabecular pattern, are important in the differential diagnosis of acinar cell carcinomas. Diagnosis of acinar cell carcinoma is confirmed and separated from PanNETs by expression of trypsin, BCL10 or lipase. Acinar cell carcinomas may also focally coexpress chromogranin A and synaptophysin. Acinar cell carcinoma that expresses neuroendocrine markers in more than 30% of all tumor cells is regarded as a MiNEN [31].

Pancreatic neoplasms that exhibit clear cytoplasm, e.g., clear cell variant of SPN, metastasis of clear cell renal cell carcinoma and solid-type serous cystic neoplasm, can be mimics of the clear cell variant of PanNET. Tumor cells that contain abundant lipid vacuoles appear to be mimics of adrenocortical neoplasm.

Mesenchymal or nonepithelial neoplasms including Ewing sarcoma, desmoplastic small round cell tumor, metastatic melanoma, SMARCB1-deficient neoplasms, and sclerosing epithelioid mesenchymal neoplasm occasionally express synaptophysin and may morphologically mimic PanNENs, mainly large cell PanNECs [32]. Ewing sarcomas are characterized by CD99, NKX2.2, and FL1, and 5–10% of Ewing sarcomas express synaptophysin [33]. Desmoplastic small round cell tumors express desmin and WT1, and variably (16–100%) express synaptophysin. Mesenchymal neoplasms usually express no or only focal cytokeratin and are negative for chromogranin A [32].

Introduction

Low-grade pancreatic neuroendocrine tumors (PanNETs) are the second most common malignancy of the pancreas, accounting for approximately 2% of newly diagnosed pancreatic malignancies. The increased diagnosis of patients with this disease has mainly been due to better imaging and diagnostic tools, and the increased use of imaging which has led to a larger number of incidentally detected tumors [1–4]. Although PanNETs are not as lethal as pancreatic adenocarcinoma (PDCA), more than 50% of patients have metastatic disease at diagnosis and the 10-year survival rate is about 40% [5]. High-grade pancreatic neuroendocrine carcinomas (PanNECs) are extremely rare, and highly lethal [6–9].

Well-differentiated PanNETs are classified as functional or nonfunctional, with the latter group being most common [10]. Functional PanNETs produce clinical syndromes with systemic effects related to the hormones that they secrete. The most common functional PanNETs are insulinomas, while glucagonomas, gastrinomas, somatostatinomas, VIPomas, and some PanNETs of mixed function comprise the rest of this group. Nonfunctional PanNETs do not secrete clinically significant hormones; rather, they grow silently, and patients often present with either an asymptomatic pancreatic mass or abdominal pain resulting from compression due to a large tumor. Surgery can be curative in the case of primary PanNETs and some cases of metastasis, but many patients present with unresectable tumors or extensive metastatic disease.

Most PanNETs are sporadic; however, they can also arise in patients with familial syndromes, most commonly in those with multiple endocrine neoplasia type 1 (MEN 1), followed by von Hippel–Lindau (VHL), neurofibromatosis type 1 (NF1) and tuberous sclerosis (TSC) [11]. Patients with one of these syndromes have germline mutations in the gene(s) that are responsible for the predisposition to the familial syndromes.

PanNECs, defined as poorly differentiated neuroendocrine neoplasms with dramatic atypia and proliferation rates typically >50%, are highly malignant neoplasms, and include entities previously classified as "small cell" and "large cell" neuroendocrine carcinomas [6–9]. There are some neoplasms which have a proliferation rate >20% but which retain an otherwise well-differentiated morphology, and these neoplasms harbor genetic alterations similar to well-differentiated PanNETs, and not those of the high-grade PanNECs [12,13]. These later neoplasms have therefore been designated as grade 3 PanNETs [14].

We now know that cancer takes many years to develop and is caused by the sequential alteration of a small number of genes that affect a smaller number of cellular processes [15]. The genomic landscapes of many tumor types have been determined, and although not everything is fully understood, these studies have provided sufficient information for developing effective approaches to reducing cancer morbidity and mortality. For similar reasons, much progress has been made in understanding the genetic alterations that underlie PanNET and PanNEC tumorigenesis. This chapter will describe what is known about the genetic landscape and epigenetics of PanNETs and PanNECs, and their clinical applications.

Genetics of Sporadic PanNETs

In order to gain insight into the genetic basis of PanNETs, whole-exome sequencing (WES) was performed in 10

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

clinically homogeneous nonfunctional PanNETs [16]. Then, the most commonly mutated genes were analyzed for mutations in 58 additional nonfunctional PanNETs. The most commonly mutated genes identified encode proteins that are involved in chromatin modification. *MEN1* had inactivating mutations in 44% of the PanNETs. *ATRX* and death domain-associated protein (*DAXX*) had mutually exclusive inactivating mutations in 18% and 25% of the PanNETs respectively, resulting in the inactivation of the ATRX/DAXX complex in 43% of the PanNETs. Approximately 14% of the PanNETs had mutations predicted to result in the activation of the mTOR pathway. Tuberous sclerosis complex 2 (*TSC2*) was inactivated in 9% of the samples, and phosphatase and tensin homolog (*PTEN*) was inactivated in 7% of the samples. In addition, there was an activating mutation in *PIK3CA*, which encodes the p110 α catalytic subunit of PI3K. *TP53* was only inactivated in 3% of the PanNETs (Table 100.1). Overall, there were about 8–23 mutations/tumor with a mean number of 16 mutations, which is low compared to most other solid tumors. Mutations in oncogenes are rare in most solid tumors, so it was not unexpected that only one sample had an activating oncogenic mutation [15].

This lack of activating mutations in oncogenes underlies the overall challenge for developing targeted therapies for PanNETs. As a result, understanding the pathways involved in the development and progression of cancers has become pivotal for developing therapeutics. A good example is the mTOR pathway. Existing therapeutic agents that inhibit this pathway do not target commonly mutated genes in the pathway, but rather target mTORC1, a downstream effector in the pathway.

As we will discuss later, inactivating mutations in *ATRX* and *DAXX* correlated with the ALT phenotype. In fact, protein expression studies in 68 PanNETs indicated that all samples with *ATRX* or *DAXX* inactivating mutations exhibited the ALT phenotype [17]. Interestingly, tumors negative for nuclear labeling of either ATRX or DAXX also showed the ALT phenotype, indicating that *ATRX* or *DAXX* genes were inactivated either by a rearrangement such as large deletions not identifiable by exome sequencing, or via epigenetic mechanisms. This study indicated that inactivation of *ATRX* or *DAXX* occurred in approximately 60% of the PanNET samples, of which 43% were caused by exomic mutations and the remaining cases most likely resulted from large deletions or epigenetic gene inactivation.

To alleviate some of the limitations of WES mentioned above, the whole genomes of 98 PanNET samples were subsequently analyzed for somatic mutations, germline mutations, and telomere repeat content [18]. Overall, the results of this study validated the major findings reported by WES analysis with small differences in the percent of samples with somatic mutations in the major driver genes involved in the tumorigenesis of PanNETs. The most frequently mutated gene was *MEN1* with 37% of the samples having inactivating mutations. *DAXX/ATRX* were inactivated in 34% of the samples and associated with the presence of ALT. Rearrangements and fusion genes, including *PTPRD* and Ewing sarcoma 1 (*EWSR1*) gene, were observed in three samples without *ATRX/DAXX* mutations. Consistent with previous results, somatic mutations in *TSC1*, *TSC2*, *PTEN*, and *DEPDC5* were observed that were predicted to activate the mTOR signaling pathway. Germline analysis revealed mutations in *MUTYH* in five patients, *BRCA2* in one patient and *CHEK2* in four patients, suggesting the involvement of DNA damage repair pathways in a subset of PanNETs. In addition, there were five patients with *MEN1,* and one patient each with *CDKN1B* or *VHL* germline mutations.

In glial tumors, *ATRX* inactivating mutations and *TERT* promoter mutations are mutually exclusive, presumably because each type of mutation results in preservation of the telomeric length appropriate for cell growth [19]. To evaluate the possibility of this occurring in PanNETs, the samples analyzed for *ATRX* and *DAXX* mutations were also evaluated for *TERT* promoter mutations. None of the 68 PanNETs had TERT promoter mutations at the hot spots shown to be mutated in many other tumor types; thus, we presume that TERT is expressed in these tumors.

The exome of sporadic functional PanNETs has only been sequenced in insulinomas. In a set of 10 insulinomas, the most commonly mutated gene was the transcription factor Ying Yang 1 (*YY1*) [20]. Sequencing of *YY1* in an additional 103 insulinomas identified a hot spot mutation in 31 of them. Overall, 30% (34/113) of the insulinomas possessed the T372R mutation in *YY1*. A more recent study focusing on the Caucasian instead of Asian population identified a much lower prevalence (13%) of *YY1* mutations in sporadic insulinomas. In the Caucasian population, the T372R mutation appeared to stratify with women and older age [21].

Pathways Altered in PanNETs

ATRX/DAXX Pathway

As noted above, approximately half of PanNETs have inactivating mutations in *ATRX* or *DAXX*. *ATRX* is located on chromosome X, and only the active copy needs to be inactivated to result in total loss of the ATRX protein expression. On the other hand, *DAXX* is located on chromosome 6, and both copies need to be inactivated for DAXX protein loss. The mutations that occur in the *DAXX* gene include single nucleotide base substitutions and indels that create frameshifts, and larger deletions of single or multiple exons, all accompanied by

loss of heterozygosity (LOH). The mutations in both *ATRX* and *DAXX* lead to inactivation of the respective gene and tumors with these mutations lack nuclear protein immunolabeling for the respective proteins, in accordance with them being tumor suppressors. The mutations are also mutually exclusive, consistent with the two genes working within the same pathway [15,17].

ATRX is a chromatin remodeling protein that interacts with DAXX and together they function as a histone chaperone complex that deposits the histone variant H3.3 into pericentric, telomeric, and ribosomal repeat sequences [22–24]. Although the mechanism underlying the action of ATRX remains unclear, recent progress has been made. ATRX is thought to be recruited, perhaps by interacting with histones, to G-quadruplex DNA where it is involved in chromatin remodeling, with consequences for gene expression and relief of replication fork stalling [25]. Consequently, its absence can impair both nonhomologous end-joining DNA repair and formation of protein complexes, resulting in changes to the epigenetic state of the DNA [26–28].

Perhaps more intriguing is the connection between the lack of ATRX or DAXX protein expression and the ALT phenotype [29]. There is telomere length attrition with every cell division resulting in telomeric lengths that are not compatible with limitless growth. Cancer cells must circumvent this issue. Telomeric length is usually maintained by TERT [30]; however, TERT is not always active. Cells with the ALT phenotype have very long telomeres whose lengths are maintained by recombination instead of by the enzymatic action of TERT [31]. Mutations in *ATRX* or *DAXX* that abolish protein expression of these proteins in PanNETs correlated with ALT [17,19,32]. *ATRX* inactivating mutations concomitant with ALT have also been identified in extrapancreatic tumor types, including glial tumors, neuroblastomas, and sarcomas, in cancer cell lines, as well as in *in vitro* immortalized ALT cell lines [19,33]. Furthermore, loss of wild-type *ATRX* expression in somatic cell hybrids segregated with ALT, whereas *ATRX* expression led to inhibition of ALT [34,35]. A greater understanding of how *ATRX* loss may result in the ALT phenotype and its connection to increased chromosomal instability was provided by a study which showed that loss of *ATRX* in cancer cells lines can promote sister telomere cohesion associated with increased recombination between sister telomeres [36].

PanNETs are also unique in that *DAXX* mutations are predominant over *ATRX* mutations, even though *DAXX* mutations are extremely rare in other tumor types with ALT, which almost exclusively have *ATRX* mutations [16,37]. The differences in the spectrum of *ATRX* mutations in various diseases and the preferential inactivation of *DAXX* in PanNETs provide fertile ground for understanding the intricacies of this pathway and its tumor-specific ALT phenotype, with the hope that a deeper understanding will lead to the therapeutic targeting of the pathway.

MEN1 Pathway

MEN1 is the most frequently somatically mutated gene in PanNETs [16,38]. This gene encodes the transcriptional regulator menin, which recruits the H3K4me3 histone methyltransferase mixed-lineage leukemia (MLL) complex [39,40]. Menin interacts with many proteins and regulates gene expression and intracellular cell signaling; it is associated with numerous cellular processes including the regulation of SMAD3 to inhibit TGFβ1-mediated inhibition of proliferation, and repression of JunD activity, regulation of homeodomain gene expression, and repression of telomerase expression [41–44]. *MEN1* mutations in PanNETs inactivate both alleles either by inactivating mutations or a combination of mutation coupled with LOH. Thus, by definition, *MEN1* is a tumor suppressor.

It appears that tumorigenesis in PanNETs is driven by alterations in both histone modification and chromatin remodeling as the overlap of *MEN1* with *ATRX/DAXX* mutations is significant (74%). *MEN1* and *ATRX/DAXX* are epigenetic drivers of cancers resulting in a plethora of epigenetic changes in the cell. Thus, it is important to determine which epigenetic alterations are the key drivers of PanNET tumorigenesis, which has obvious implications for therapeutic exploitation of the associated pathways.

mTOR Pathway

The mTOR signaling pathway integrates environmental signals to regulate growth and homeostasis. mTOR is an atypical serine/threonine protein kinase that interacts with several proteins to form two key complexes in the pathway named mTOR complex 1 (mTORC1) and 2 (mTORC2), each of which mediates different upstream inputs and has different downstream outputs.

A number of tumor suppressors and oncogenes commonly mutated in cancers are upstream of mTORC1, including the PTEN/PIK3CA pathway, the RAS/RAF pathway, TSC1/2, NF1, and LKB1. Sequencing of PanNETs revealed somatic mutations in *TSC2*, *TSC1*, *DEPDC5*, *PTEN*, and *PIK3CA* genes in 16% of samples, all of which are predicted to activate the mTOR pathway, conasistent with its progrowth effects on cells. Downstream effectors of the pathway involve 4E-BP1, which in turn regulates hypoxia inducible factor 1 (HIF1a), a target of VHL, and S6K1 resulting in increased

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. proliferation signals, regulation of metabolism, and increased protein synthesis [reviewed in 45]. Inhibitors of the mTOR pathway have shown benefit in patients with different tumor types, including PanNETs; however, correlations between pathway mutations and the observed benefits have not yet been fully established [46].

Based on results from other tumor types, we hypothesize that patients with tumors with mTOR pathway mutations will respond better to therapies targeting this pathway [41]. However, in clinical trials, the number of patients with PanNETs that benefited from treatment with everolimus, which targets the mTOR pathway, was larger than the number of PanNETs with mutations in the mTOR pathway [16,46]. However, this is an extrapolation as the PanNETs from the patients included in the study were not tested for mutations. It is worth noting that for such a complicated pathway, there could be other means of activation besides mutations. Related to this, expression studies resulted in the observation that expression of genes in the mTOR pathway is upregulated in PanNETs [47]. Nevertheless, a good study to test the companion diagnostic potential of the mutational status of the pathway would be important.

High-grade Neuroendocrine Carcinomas

In contrast to well-differentiated PanNETs, the *DAXX/ATRX* and *MEN1* genes are not targeted in most high-grade PanNECs [6,48,49]. Instead, the *RB1* and *TP53* genes are commonly somatically mutated in PanNECs [6]. Yachida and colleagues extensively studied a series of PanNECs (small cell and large cell neuroendocrine carcinomas) and found the p53 expression was altered in 95% and Rb in 74% of the PanNECs [6]. Abnormal immunolabeling of p53 and Rb proteins correlated with the intragenic mutations in the *TP53* and *RB1* genes. By contrast, DAXX and ATRX labeling was intact in virtually all of these same carcinomas. These genetic differences indicate that the biology and process of tumorigenesis are distinct in PanNETs and PanNECs, and that poorly differentiated PanNECs do not result from progression of the well-differentiated PanNETs to a less differentiated state.

The increased genetic understanding of these neoplasms resulted in changes in the 2019 WHO classification [16]. Tumors with a high proliferation rate (>20%) that maintain their well-differentiated neuroendocrine cytology are now classified as grade 3 PanNETs as they have the same mutational profile as do lower grade PanNETs. In addition, PanNECs with small cell morphology are lumped together with PanNECs with large cell morphology because of their overlapping mutational profiles [50].

A comprehensive analysis of 115 cases of neuroendocrine neoplasms of gastrointestinal system (GIS-NEN), specifically 60 GIS-NECs (18 pancreatic, 14 gastric, 10 biliary, nine colorectal, six ampullary, three esophageal) and 55 GIS-NETs (48 pancreatic, six colorectal, one nonampullary duodenal), that included WGS/WES, transcriptome sequencing, DNA methylation, and ATAC-seq, allowed comparison of genetic and epigenetic features of these neoplasms [51]. This study validated that PanNETs are genetically distinct from PanNECs. Overall, GIS-NECs are genetically distinct from GIS-NETs. Although there were overlapping features between NECs of different organ sites, there were significant differences between PanNECs and extrapancreatic NECs. Furthermore, the authors of the study proposed a classification of PanNECs into two groups, a "ductal-type" and an "acinar-type."

Comparison of PanNET Genetic Landscape to Other Pancreatic Neoplasms

The genetic landscape of well-differentiated PanNETs is fundamentally different from that of the more aggressive pancreatic adenocarcinoma (PDAC) (see Table 100.1). *KRAS* mutations that are not found in neuroendocrine tumors are present in almost 95% of PDACs. In addition, PDACs have a high prevalence of mutations in *SMAD4*, *CDKN2A*, and *TP53* genes, but no mutations in *DAXX*, *ATRX*, or *MEN1* [52,53].

The genetic alterations found in PanNETs are also distinct from those found in the other neoplasms of the pancreas. Serous cystic neoplasms are characterized by *VHL* gene mutations, solid-pseudopapillary neoplasms by *CTTNB1* mutations, intraductal papillary mucinous neoplasms by alterations in *KRAS*, *GNAS*, *RNF43*, *p16/CDKN2A*, and *TP53*, mucinous cystic neoplasms by mutations in *KRAS*, *RNF43*, *p16/CDKN2A*, and *TP53*, and acinar cell carcinomas by multiple complex alterations including mutations in *JAK1*, *BRAF*, and *APC*, among others [52,54,55].

The distinct mutational profile of each tumor type of the pancreas suggests that mutational analyses may be used to help classify tumor type in the future [56].

Finally, among neuroendocrine tumors, the targeting of the *ATRX/DAXX* pathway and ALT is relatively specific for those tumors that arise in the pancreas. This suggests that ALT status could be used to clarify organ of origin in metastatic neuroendocrine tumors of unknown primary [57].

Familial Syndromes

MEN 1 is an autosomal dominant syndrome caused by germline mutations in the *MEN1* gene on chromosome 11, which is the gene most frequently somatically mutated in sporadic PanNETs [58]. As previously mentioned, *MEN1* is a tumor suppressor gene that follows the two-hit paradigm. The first hit in individuals with MEN 1 is an inactivating inherited mutation. The second hit, an inactivating somatic mutation or loss of heterozygosity of the remaining wild-type allele, occurs in the tumors. Tumors of the pancreas are the second most common manifestation of the MEN 1 syndrome. Most of the PanNETs in MEN 1 patients are nonfunctional, although about 10% of them are insulinomas. They typically appear as multiple microadenomas (<0.5 cm); however, in many cases, like the sporadic PanNETs, they can grow larger and even metastasize to other organs [59,60].

Study of the genetics of PanNETs in the context of the MEN 1 syndrome has shown that *MEN1* inactivation precedes *ATRX/DAXX* inactivation and the concomitant appearance of ALT [32]. In this study, 109 well-differentiated PanNETs from 28 patients with MEN 1 syndrome were tested for expression of ATRX and DAXX and for the presence of ALT by immunolabeling as a proxy for the genetic inactivation of the genes that encode for these proteins. The lesions included 47 neuroendocrine microadenomas (<0.5 cm), 50 pancreatic neuroendocrine tumors (>0.5 cm), and 12 pancreatic neuroendocrine tumor lymph node metastases. All of the lesions had loss of function of the MEN1 protein by definition, since they were present in patients with MEN 1 syndrome; thus, this was the first and presumably the initiating event in these tumors. ATRX/DAXX expression was intact in all of the 47 microadenomas, which were also negative for ALT. Loss of ATRX/DAXX expression was only observed in tumors larger than >3 cm. These tumors were also ALT positive, which is consistent with the already documented role of ATRX/DAXX loss in the development of ALT. In addition, in the samples with concurrent metastases, the genetic alterations in the primary and metastatic tumors were the same. The progression from *MEN1* inactivation to *ATRX/DAXX* inactivation and appearance of ALT as the tumor size and the risk of metastasis increased, which was observed in the MEN 1 syndrome-associated PanNETs, most likely exists in the sporadic PanNETs as well. However, *ATRX/DAXX* inactivation in sporadic pancreatic neuroendocrine microadenomas was much higher [61].

Von Hippel–Lindau syndrome is caused by germline mutations in the tumor suppressor *VHL* on chromosome 3. The VHL protein controls the degradation via ubiquitination of HIF1, and loss of VHL leads to tumor growth and angiogenesis. HIF1 regulation also has been proposed to be downstream of the mTOR pathway. Patients with VHL syndrome develop a number of different benign and malignant neoplasms, and approximately 12–15% of them develop nonfunctional PanNETs. Most of these tumors have a clear cell morphology and are well differentiated, but some are aggressive, and they can metastasize [62,63].

PanNETs also arise, albeit less frequently, in patients with NF1 and TSC syndromes [11]. NF1 is caused by germline mutations in *NF1*, whereas TSC results from germline mutations in *TSC1* or *TSC2*. All three of these genes are tumor suppressors and are associated with the extensive mTOR pathway [64,65]. NF1 acts more distally upstream of mTORC1, regulating the KRAS arm of the pathway. The TSC1/TSC2 complex inhibits mTORC1 activation. Mutations in *TSC2* were the most common mTOR pathway mutations observed in sporadic PanNETs.

The prevalence of PanNETs in these syndromes is in accordance with the presence of the affected pathways in sporadic PanNETs, with *MEN1* mutations occurring in 44% of PanNETs and mTOR only occurring in 16% of these tumors [16]. Further studies on the genetic changes in syndromic PanNETs will provide an understanding of the pathways that drive PanNET tumorigenesis.

Epigenetics

PanNETs can be classified into three groups according to their RNA profiles: well-differentiated islet cell tumors/insulinomas, poorly differentiated tumors, and gene mutation-enriched subtypes. The first two classification groups are not surprising as PanNETs and PanNECs are two different tumor types. The differences between well-differentiated and gene mutation-enriched groups are intriguing in that they could reflect groups with different clinical behaviors.

Targeted CpG promoter methylation analysis of 46 PanNETs revealed hypermethylation in *MEN1* in 19% of tumors tested and in *MGMT* in 17% in tumors tested [66]. Genome-wide methylation analysis of 53 PanNETs identified significant differences in methylation profiles between tumors of different grades and between tumors with or without *ATRX*/*DAXX* mutations. However, this clustering was not perfect as some tumors with mutations in these genes clustered with normal controls. Interestingly, there were significant differences in the methylation profiles between PanNETs with *ATRX* mutations and those with *DAXX* mutations [37].

RNA sequencing followed by RNA expression analysis of 33 PanNETs, 19 with mutations in *ATRX/DAXX/MEN1*

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and 14 without mutations in these genes, identified two distinct clusters [67]. The profile of the PanNETs with mutations in *ATRX/DAXX/MEN1* was reminiscent of that from a pancreatic α cell with highly expressed aristaless-related homobox gene (ARX) and low expression of pancreatic duodenal homeobox 1 (PDX1), suggesting a possible cell origin of the tumor. Similar results based on enhancer signatures were reported by Cejas et al. [68]. Genome-wide DNA methylation profiling of PanNETs classified them in α-like and β-like, stratifying with mutations in *ATRX/DAXX/MEN1* and no mutations in these genes along the lines presented in Chan et al. [67,69]. However, the classification included an intermediate profile indicating the need for further refinement of the groups.

Another study classified 84 sporadic PanNETs into three groups based on DNA methylation which also stratified with genetic alterations. PanNETs in the T1 group did not have mutations in *ATRX/DAXX/MEN1* and were enriched in functional tumors. PanNETs in group T2 had mutations in *ATRX/DAXX/MEN1* and high expression of *MGMT*. PanNETs in group T3 had mutations in *MEN1* with recurrent loss of chromosome 11. This group was enriched in grade G1 PanNETs [70]. The aforementioned studies provide concordant results in that there is a genetic classification of PanNETs accompanied by epigenetic changes reflected in RNA expression and methylation profiles; however, these classifications do have overlap and are not yet well defined. Furthermore, these studies include both functional and nonfunctional PanNETs.

Clinical Implications

The genetic landscape reflects the different biology and clinical manifestations of pancreatic neuroendocrine neoplasms and has clinical ramifications. First, genetics can be used to unambiguously classify the different lesions. Second, the differences in the genetics suggest different types of treatment. Unfortunately, treatments are not available that can target the most common mutations in PanNETs, *MEN1* and *ATRX/DAXX* mutations. The relationship between loss of *ATRX/DAXX* with ALT, recombination and DNA repair suggests that synthetic lethality could be feasible with agents that interfere with these pathways. However, this has not yet been proven.

ATRX/DAXX mutations in PanNETs have been associated with prognosis. In a study of 142 well-differentiated PanNETs, loss of ATRX and DAXX and presence of ALT correlated with higher tumor stage and a worse prognosis, perhaps a reflection of *ATRX/DAXX* mutations being a late event in PanNET tumorigenesis [71]. However, when only the subset of metastatic patients was considered, loss of ATRX and DAXX was associated with longer survival [62]. This latter observation is in accordance with the initial observation that patients with metastatic PanNETs harboring *MEN1*, *ATRX*, and *DAXX* mutations showed better prognosis and longer survival [18]. Similarly, in an independent study of 43 patients with liver metastasis managed with resection, loss of ATRX/DAXX was associated with better overall survival [57]. One interpretation of this is that tumors with *ATRX/DAXX* inactivating mutations comprise a subgroup with a different clinical presentation than the PanNETs without inactivation of these genes.

Furthermore, as noted earlier, in a comparison between metastatic lesions in the liver from patients with PanNETs or gastrointestinal carcinoid tumors, the presence of ALT in the metastatic lesion was a useful biomarker to predict that site of origin of metastatic lesions to the liver is a neuroendocrine tumor of the pancreas in cases where the primary site is unknown [57].

Although the classifications of PanNETs mentioned above based on epigenetic profiles indicate that different PanNETs have different potential clinical outcome [67–69], it is not yet clear which biomarkers provide accurate prognosis for nonfunctional PanNETs. Expression of ARX and PDX1 by immunolabelling, as well as mutational status of *ATRX/DAXX* by immunolabelling and fluorescence *in situ* hybridization (FISH) for ALT, were evaluated in 1322 NETs from multiple institutions. All NETs were nonfunctional, 561 primary PanNETs, 107 metastases of PanNETs, and 654 nonpancreatic nonfunctional primary and metastases NETs. ATRX/DAXX and ALT status were independent prognostic factors. ATRX/DAXX-negative and ALT-positive PanNETs had worse five-year relapse-free survival (RFS). In contrast, ARX/PDX1 expression did not independently correlate with RFS [72]. These data provide evidence that ATRX/DAXX immunolabeling and ALT FISH should be considered as prognostic biomarkers for nonfunctional PanNETs [72]. Given the issues with diagnosis of certain neuroendocrine neoplasmas [73], ATRX/DAXX and ALT are highly diagnostic biomarkers to indicate the origin of NET metastasis of unknown primary tumor [72].

Of all the mutations identified in PanNETs, those in the mTOR pathway show promise as therapeutic target, as it is thought that PanNETs with mTOR pathway mutations upstream of mTORC1 will derive benefits from mTOR inhibitors. However, this has yet to be proven in clinical trials. A trial has been reported that will test this hypothesis [74]. It is worth noting that the mTOR pathway is complex; thus, mutations in other genes or via epigenetic mechanisms may activate this pathway in

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

PanNETs. Even so, not only people with tumors with the described mTOR pathway mutations will show benefit from the therapies, but also people with "cryptic," at least for now, alterations of the mTOR pathway.

Everolimus was approved by the FDA in 2011 for patients with advanced PanNETs, based on the results of the RADIANT III trial [46]. In this trial, single therapy with everolimus was compared to the best supportive care for advanced PanNETs. The majority of patients had previously been treated with different therapies. Compared to placebo, everolimus led to increased progression-free survival (11 vs 4.6 months).

Sotorasib, a KRAS inhibitor, has been approved for the treatment of lung cancers. In the future, this could be a possible therapeutic option for PanNECs with *KRAS* mutations. A potential future therapy for tumors with *TP53* mutations has been proposed based on bispecific antibodies that target mutant p53 [75]. This approach is in the very early stages but if successful, it could be considered for treatment of *TP53* mutant PanNECs.

Conclusion

Over the last several years, the studies mentioned above have increased our understanding of the genetic alterations and intracellular pathways that drive PanNET tumorigenesis. Although much remains to be determined, for example identification of the driver genes in PanNETs that do not have mutations in *MEN1*, *ATRX*, or *DAXX*, we have enough information to develop clinical applications based on the genotype of these tumors [76]. Future studies should clarify which companion diagnostics should be available for therapies, such as everolimus, as many patients do not respond to this drug. In those who are responsive, the overall increase in survival is months rather than years. New therapies are needed for the management of patients with PanNETs. Therefore, efforts should be invested in understanding and therapeutically targeting the ATRX/DAXX and MEN1 pathways. It is clear that molecular genetics have provided new opportunities to improve the clinical management of patients with PanNETs.

What is the Origin of Pancreatic Endocrine Tumors?

Aurel Perren[1], Iacovos P. Michael[2], and Ilaria Marinoni[1]

[1] *Institute of Pathology, University of Bern, Bern, Switzerland*
[2] *Biological Sciences, Sunnybrook Research Institute, Toronto, Canada*

Introduction

Historically, Pierre Masson proposed an origin of gastroenteropancreatic neuroendocrine tumors (GEP-NET) from gastrointestinal endocrine cells [1]. This idea was challenged by the APUD-oma concept of Pearse with the hypothesis that GEP-NETs would arise from APUD (amine precursor uptake and decarboxylation) cells, which migrated to endoderm from the neural crest [2]. More recent work based on transcriptomic data, such as expression of transcription factors, as well as genetically engineered mouse models established the original idea of diffuse neuroendocrine cells as the origin of GEP-NETs. Lately, DNA methylation markers have been shown to be useful in providing information on the potential cell of origin in different cancer types [3,4].

In pancreatic neuroendocrine tumors (PanNETs), different molecular subtypes based on mutational pattern and gene expression have been reported, and some of these changes show associations with type of hormone production and thereby possibly cell of origin [5]. Recent data support the islet α- and β-cells as a potential origin of PanNETs [6,7]. Additional PanNET subgroups may also arise from other endocrine cell types as well as from precursors. Interestingly, pancreatic neuroendocrine carcinoma (PanNEC) could arise from acinar or ductal cells in addition to precursors [8].

Mouse Models

Genetically engineered mouse models (GEMMs) have been instructive in the understanding of tumorigenesis and the role of various genetic and nongenetic modifications (Table 101.1). Over the years, numerous GEMMs have been developed, aiming to understand the cell of origin and the role of various genetic alterations during the progression of PanNETs [9–11]. Most of the studies have focused on three cell types: the pancreatic progenitors, and the endocrine α- and β-cells. Herein, we focus on studies examining the role of the most frequently mutated genes in PanNETs, i.e., *MEN1*, *DAXX/ATRX*, *VHL*, and mTOR pathway genes (e.g., *Pten*), and the role of the p53 and pRb tumor suppressors [12–14]. Although *TP53* and *RB1* gene mutations are exceptionally rare in PanNETs, alterations of upstream regulators often lead to their inactivation [15,16].

Inactivation of the *Men1* in mouse progenitor cells of the endocrine and exocrine pancreas using a Pdx-1 driven Cre leads to development of only endocrine tumors with expression of insulin, without any exocrine malignancy [17]. The specific derivation of insulinomas could be due to the persistent Pdx-1 expression in mature β-cells, which presumably allows for complete *Men1* inactivation, in contrast to the transient expression in the progenitor cells (Figure 101.1). It might also be due to the unique susceptibility of β-cells to *Men1* inactivation; however, this is unlikely, since as mentioned below both α- and β-cell specific *Men1* deletion leads to tumorigenesis. Genetic inactivation of *Men1* along with *Daxx* in the pancreatic progenitor cells using the Pdx-1 driven Cre resulted in the generation of insulinomas that had the same overall survival as *Men1* inactivation [18]. Inactivation of the *Vhl* gene in pancreatic progenitors using the Pdx-1 driven Cre leads to the development of pancreatic cysts, microcystic adenomas, and some hyperplastic islets [19]. The latter phenotype recapitulates the nonfunctioning neoplasms in patients with VHL disease [20]. Notably, *Vhl* specific deletion in either

Table 101.1 PanNET mouse models with respective cells of origin

Tumor model (mouse strain)	Cell of origin	Promoter	Genetic modification	Phenotype	Metastasis	Reference
PDX1-Cre; $Men1^{loxP/loxP}$	Pancreatic progenitor cells/ β-cells	PDX1 promoter	*Men1* inactivation	Insulinoma	Not reported	[17]
PDX1-Cre; $Men1^{loxP/loxP}$; $Daxx^{loxP/loxP}$	Pancreatic progenitor cells/ β-cells	PDX1 promoter	*Men1* and *Daxx* inactivation	Insulinoma	Not reported	[18]
PDX1-Cre; $Vhl^{loxP/loxP}$	Pancreatic progenitor cells	PDX1 promoter	*Men1* inactivation	Cysts, microcystic adenomas (hyperplastic islets)	Not reported	[19]
Glu-Cre; $Men1^{loxP/loxP}$	α-Cells	Glu promoter	*Men1* inactivation	Glucagonoma; insulinoma (via transdifferentiation)	Not reported	[21]
Ren-Cre; $p53^{loxP/loxP}$; $Rb^{loxP/loxP}$	α-Cells	Renin promoter	*Tp53* and *Rb1* inactivation	Glucagonoma	LN and liver (glucagon positive)	[23]
RIP-Cre; $Men1^{loxP/loxP}$	β-Cells	Rat insulin promoter	*Men1* inactivation	Insulinoma (progressive downregulation of insulin expression)	Not reported	[24]
MIP-Cre; $Men1^{loxP/loxP}$	β-Cells	Mouse insulin promoter	*Men1* inactivation	Insulinoma	Not reported	[25]
MIP-Cre; $Men1^{loxP/loxP}$; $Pten^{loxP/loxP}$	β-Cells	Mouse insulin promoter	*Men1* and *Pten* inactivation	Insulinoma	Not reported	[25]
RIP1-Tag2 (RT2;C57Bl/6N)	β-Cells	Rat insulin promoter	SV-40 TAg-mediated inhibition of p53 and pRb	Insulinoma (rare nonfunctional MLP PanNETs)	Rare	[26]
RIP1-Tag2 (RT2;AB6F1)	β-Cells	Rat insulin promoter	SV-40 TAg-mediated inhibition of p53 and pRb	Insulinoma (IT) and nonfunctional (MLP) PanNETs	LN and liver (from nonfunctional MLP PanNETs)	[29]

LN, lymph node; MLP, metastasis-like primary; PanNET, pancreatic neuroendocrine tumor.

α- or β-cells has no phenotype, indicating a susceptibility of pancreatic progenitor cells to *Vhl* inactivation [19].

α-Cell specific inactivation of *Men1*, using glucagon-driven Cre, leads to glucagonomas [21]. Intriguingly, glucagonomas transdifferentiate to insulinomas in advanced stages of the disease [21]. Similarly, in humans the rarely occurring malignant insulinomas share molecular features closer to nonfunctioning (ATRX-DAXX-MEN1 mutant) PanNETs, indicating that such a transdifferentiation could also occur [22]. Conditional deletions of *Tp53* and *Rb1* using a Renin-driven model also leads to transformation of α-cells and development of glucagonoma [23]. However, in contrast to the *Men1* inactivation, the authors did not report transdifferentiation to insulinomas. Notably, the glucagonomas with deleted *Tp53* and *Rb1* gave rise to aggressive tumors that metastasized to the lymph nodes and liver [23], indicating a possible malignant PanNET phenotype originating from α-cells.

β-Cell specific inactivation of *Men1*, using a transgenic mouse in which Cre is expressed under the rat-insulin promoter, leads to the development of insulinomas [24]. During the progression of the disease, the authors observed marked downregulation of insulin, suggesting dedifferentiation and progression towards nonfunctional (NF) PanNETs. β-Cell specific inactivation of *Men1* and *Pten*, using mouse lines expressing Cre under either the mouse-insulin promoter or the rat-insulin promoter, dramatically accelerated disease progression compared to inactivation of *Men1* alone [25]. The expression of insulin levels in advanced lesions was not characterized; therefore, it is unknown whether *Men1* along with *Pten* inactivation also leads to dedifferentiation. According to the studies mentioned above, inactivation of *Men1* alone or with *Pten* activation does not lead to metastasis.

The SV40 large T antigen (TAg) protein suppresses the function of the tumor suppressor proteins p53 and pRb. Therefore, cell specific TAg expression resembles suppression of the p53 and pRb protein function due to the increased levels of upstream negative regulators during the progression of PanNETs. Specifically, β-cell specific

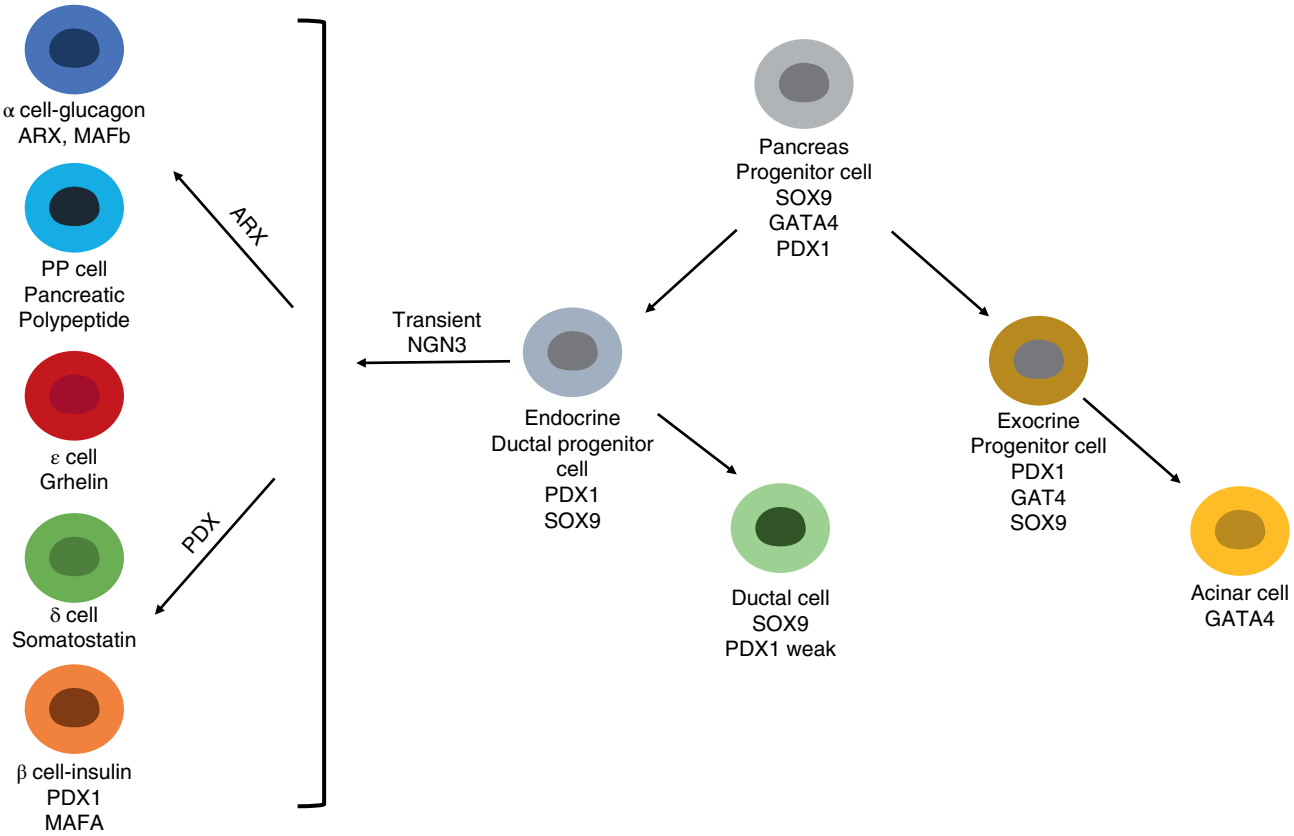

Figure 101.1 Simplified scheme of development of pancreatic cells.

TAg expression using the rat insulin promoter, in the RIP1-Tag2 (RT2) mouse model, leads to a stepwise development of insulinomas [26].

Transcriptomic characterization of primary lesions in the RT2 PanNET mouse model revealed two distinct molecular subtypes: islet tumor (IT) subtype and metastasis-like primary (MLP) subtype [27,28]. The IT subtype comprises insulinoma tumors that are not invasive and rarely metastatic, while the MLP subtype is characterized by highly invasive and metastatic tumors, that have a similar transcriptomic program to liver metastasis. Sadanandam et al. have shown that IT and MLP subtypes also exist in human PanNETs [28]. The IT subtype is made up mostly of functional G1-PanNETs and the MLP subtype by nonfunctional G3-PanNETs. Saghafinia et al. demonstrated that MLP tumors (i.e., high-grade, NF-PanNETs) arise from IT tumors (i.e., low-grade, insulinomas) via dedifferentiation following a reverse trajectory along the developmental pathway of β- cells [29]. This dedifferentiation results in the downregulation of mature β-cell markers and the activation of pancreatic progenitor markers (see Fig. 101.1).

In the RT2 mouse model, the IT-to-MLP transition takes place during the early stages of tumorigenesis and constitutes a distinct step of tumorigenesis. Notably, this transition temporarily precedes the accelerated proliferation of cancer cells. The latter suggests that some patients with low-grade PanNETs, e.g., low proliferation/Ki67 index, might have already undergone dedifferentiation, i.e., IT-to-MLP switch, and acquired prometastatic capabilities.

In addition to origin of α-, β-, and progenitor cells, the various GEMM models revealed the cell plasticity of PanNETs, which can lead to phenotype and subtype switch via mechanisms of trans- and dedifferentiation. Additional mouse models are necessary to systematically examine the effect of the inactivation (or activation) of the combination of genes associated with PanNET progression as well as to better define the cell of origin. For example, while current studies support the notion that inactivation of the p53 and pRb pathways facilitates the development of more invasive and metastatic lesions, further studies are needed to examine this in the context of *Men1* and *DAXX*/*ATRX* inactivation.

Human PanNET/Familial Syndromes

Observation of the very early steps of tumorigenesis allows us to gain insights into the microanatomic localization of tumorigenesis and thereby indicate (localization of) cells

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of origin. While such early tumors are difficult to detect, the multiple endocrine neoplasia (MEN) familial endocrine tumor syndromes are characterized by development of multiple tumors in various organs as well as within the same organ. For example, the multiple endocrine neoplasia type 1 (MEN 1) and vonHippel–Lindau syndromes are characterized by the presence of microadenomatosis of the pancreas—the occurrence of multiple microscopic endocrine microtumors.

A detailed analysis of over 300 microadenomas from pancreatic resection specimens of patients suffering from PanNET in the setting of the MEN1 syndrome showed most frequently expression of glucagon (53%), followed by pancreatic polypeptide (20%), insulin (15%), and somatostatin (5%) [30]. This distribution does not represent the abundance of respective islet cells, suggesting an increased susceptibility of α- and PP-cells to *MEN1* mutations. While these microadenomas express one hormone homogeneously, single interspersed cells expressing other islet hormones were observed, indicating islet origin of microadenomas and thereby islet origin of PanNET.

Knowing that allelic loss of the *MEN1* wild-type allele is a very early step in tumorigenesis in MEN 1 patients, a combined immunofluorescence/FISH analysis for insulin, glucagon, and the *MEN1* locus (on 11q13) enables the detection of potential monoclonal lesions inside or outside islets. Microadenomas of the pancreas showed allelic loss of the *MEN1* region in the vast majority of cases. Different patterns of loss of heterozygosity (LOH) with or without concomitant loss of centromere 11 show that individual microadenomas had independent second hits and were therefore unrelated. Single interspersed cells with expression of different islet hormones showed retention of both *MEN1* alleles, and therefore were not part of the microadenomas. This observation supports the scenario of development of microadenomas in islets [31] (Fig. 101.2). Furthermore, small clusters with expression of one single hormone were detected, both in islets (5×) as well as in ducts (1×) or in the exocrine parenchyma (1×). These monohormonal endocrine cell clusters (MECCS) all showed LOH of the MEN1 locus, and therefore represent tiny neoplastic lesions (see Fig. 101.2).

These results suggest that the genesis of PanNET is most frequently in islets, and rarely in ducts or the parenchyma. Overall, these results support the notion of development of glucagon- and insulin-positive PanNET in islets, where normal α- and β-cells are located, and the rare development of PanNET in ducts and the exocrine stroma, where rare interspersed endocrine cells can be found. The possibility of development of PanNET from putative endocrine stem cells in islets, and more rarely ducts or parenchyma, cannot be excluded.

Hyperplastic islets are a very rare phenomenon in the setting of MEN 1. Indeed, enlarged islets with increased number of α- and β-cells in a disorganized fashion with slightly increased proliferation rate are observed, but this step seems unnecessary for the development of microadenomas. In the above study, only one MECC was found in such a hyperplastic islet.

In other genetic diseases that lead to microadenomatosis, a step of hyperplasia in the sequence of development of microadenomas is possible. Both in insulinomatosis (homozygous *MAFA* mutations) and glucagon-cell adenomatosis (homozygous glucagon receptor [*GCGR*] mutations), hyperplastic islets are a frequent finding besides microadenomas [32,33].

In summary, in MEN 1 patients microadenomas frequently develop in islets, as indicated by nonneoplastic islet cells found in microadenomas and by the presence of MECCS in islets. Glucagon-producing microadenomas are the most frequent, while insulin-producing microadenomas are rare despite the much higher number of β-cells compared to α-cells, indicating a higher susceptibility of α-cells to *MEN1* mutations.

Molecular Evidence on Human PanNET

Mutation Signatures Depending on Hormone Production

Sporadic PanNETs present a heterogenous pattern of genetic drivers. As for the familial disease, *MEN1* is mutated in almost 44% of sporadic PanNETs [12]. Mutations in *DAXX* (death domain-associated protein) and *ATRX* (α-thalassemia/mental retardation syndrome X-linked) are found in almost 40% of PanNETs, often in association with *MEN1* [34]. Other less frequent mutations include members of the mTOR pathways such as *PTEN*, *TSC2*, and *PIK3CA*, and the epigenetic regulators *SETD2* and *MLL3* [12].

Insulinomas, which are the most common functioning PanNET, have a unique genetic background with recurrent mutations (T372R) in the transcription factor gene *YY1* (Ying Yang 1) in about 25% of cases [35]. *YY1* mutations have not been identified in patients with NF-PanNETs. On the other hand, insulinomas only rarely present mutations in *MEN1* and *DAXX/ATRX* [13]. Therefore, insulinoma and NF-PanNET development seems to follow different molecular pathways, which presumably reflects a different cell of origin. Indeed, while, not surprisingly, insulinomas express PDX1 (pancreatic and duodenal homeobox 1), a transcription factor responsible for β-cell differentiation, the majority of NF-PanNETs are positive for ARX (aristaless related homeobox), which

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 101.2 (a) Glucagon-producing microadenoma with nonneoplastic β-cell. GLU: Immunohistochemical staining for glucagon showing monohormonal expression typical for microadenomas. Tumor cells show loss of both MEN1 locus and C11 locus. Note the normal distribution of α-cells in nonneoplastic islets on the lower right. INS: Immunohistochemical staining for insulin showing single nonneoplastic β-cells, showing a retained *MEN1* allele in the FIHS analysis (red insulin, green MEN1 locus). (b) PanNET precursors (MECC): monohormonal endocrine cell clusters (MECC) arising in islets, parenchyma, and duct. Monoclonality by FISH was shown in glucagon-positive trabecular parts. These MECC are surrounded by cytologically normal rim of β-cells and α-cells, retaining islet structure.

instead drives the differentiation [6,7,22] of the α-cell lineage (Fig. 101.3). Interestingly, DAXX/ATRX loss is found only in malignant insulinomas in correlation with ARX positivity [22], indicating a transdifferentiation from α-cells, as observed in some mouse models.

Malignant and indolent insulinomas seem to follow different tumorigenic mechanisms: while indolent small insulinomas express the β-cell differentiation marker PDX1 consistent with β-cell origin, malignant ones express the endocrine transcription factor ARX inconsistent with normal β-cell differentiation.

Epigenetic Similarities to α- and β-Cells

Epigenetic signatures and specifically methylation patterns are now considered a robust method to identify cells of origin across tissues and different cancer types [36,37].

The methylation state is established during embryonic development. This generates a tissue-specific chromatin template, which is extremely stable and maintained for the rest of an organism's life. Each tissue type has specific DNA methylation profiles, which differ minimally across individuals. This allows identification of cell and tissue

(b)

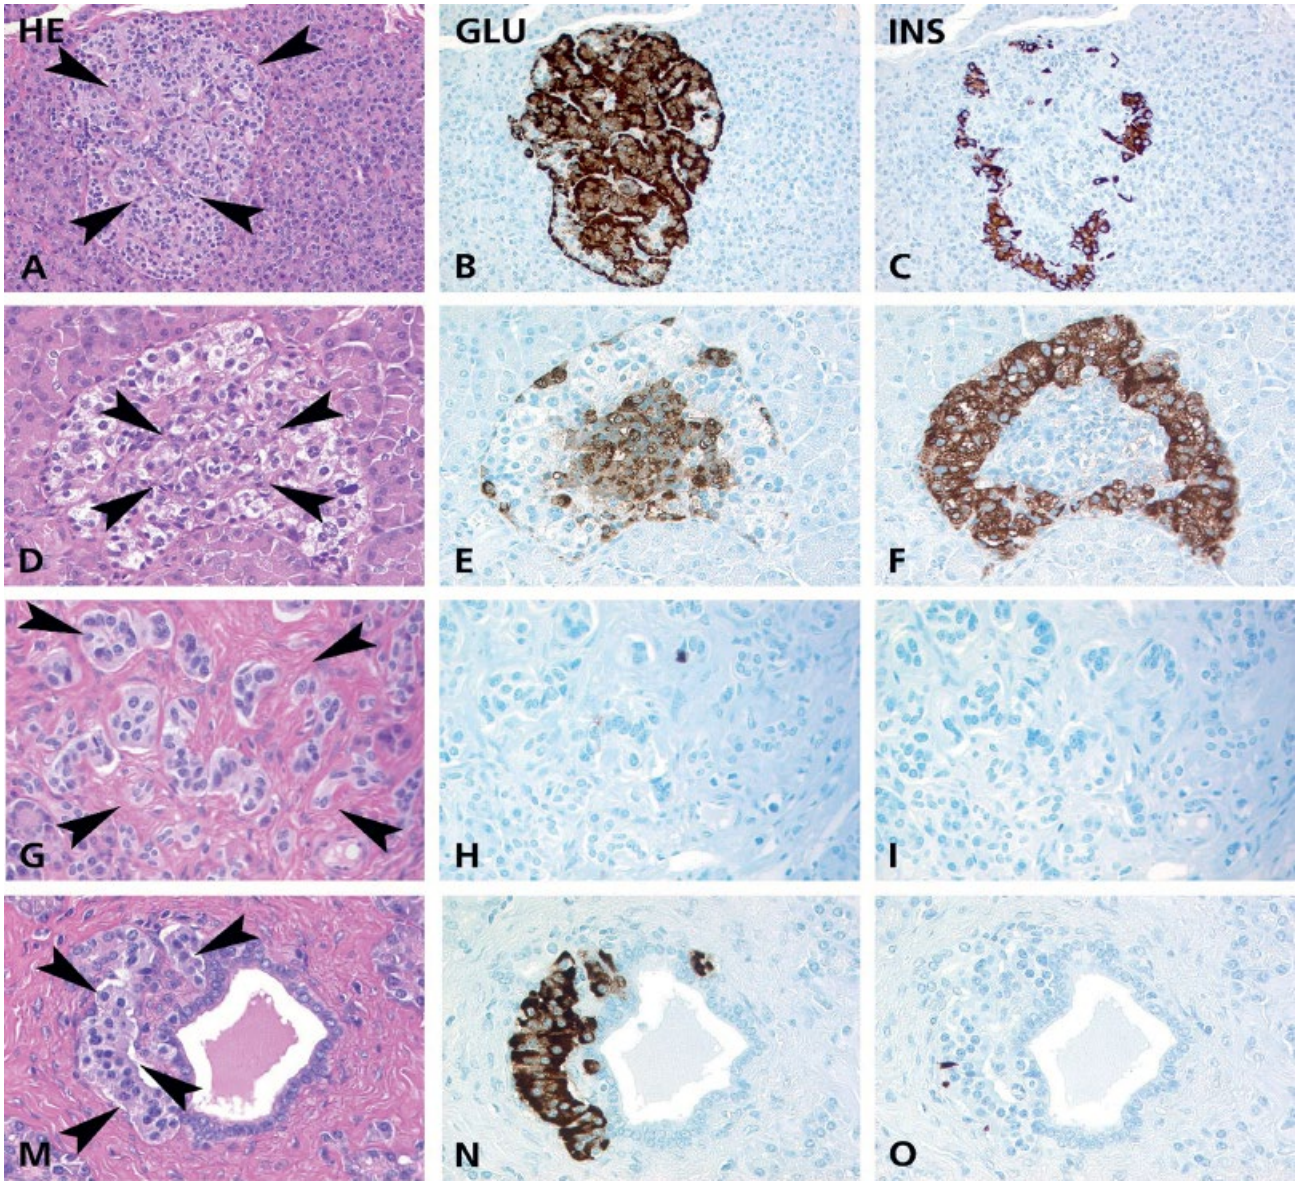

Figure 101.2 (Continued)

type based on DNA methylation profile. In addition, DNA methylation pattern allows discrimination of stem and progenitor cells from adult tissues [36]. For these reasons, DNA methylation profiles are extremely powerful in identifying subgroups of tumors as well as tissues of origin [36,38].

Recently, H3K27ac super enhancer profiles identified two major subtypes of PanNETs [6]. These subtypes comprise tumors with an α-like signature expressing ARX and tumors with a β-like signature expressing PDX1. A small fraction of PanNETs presented expression of both transcription factors or neither of them. DNA methylation profiles also classified PanNETs according to epigenetic similarity to α-cells and β-cells [7,39,40]. Specifically, based on DNA methylation profiles, three main groups of PanNETs can be distinguished: β-like and α-like tumors, respectively very similar to β- and α-cells, and a group of intermediate tumors, which seem to progressively lose cell differentiation [7]. β-Like PanNETs mainly include insulinomas while α-like PanNETs include small, grade 1 PanNETs enriched for *MEN1* mutations only. Intermediate PanNETs are instead of advanced stage, with high metastatic risk, mainly mutated in *MEN1* together with *DAXX/ATRX*.

Intermediate PanNETs mutated in *MEN1/DAXX/ATRX* (*ADM*) maintain some features of α-cells, including specific transcription factors profiles [7] Both α-like and intermediate tumors express ARX, while β-like PanNETs are PDX1 positive.

These data suggest that α-like tumors mutated in *MEN1* originate from endocrine α-cells and can progress into intermediate-ADM tumors upon *DAXX/ATRX* mutation acquisition and progressive loss of cell differentiation (see Fig. 101.3). While occasionally stem cell markers are expressed in intermediate tumors, an origin from progenitor or stem cell is not yetproven. Of note, ARX is already expressed in endocrine precursor and in both α- and γ-cells [41,42].

β-Like tumors instead seem to originate directly from β-cells, giving rise to insulinoma. These tumors separate very clearly from the rest according to the β-cell transcription factors [7]. Interestingly, a group of aggressive tumors (metastasis-like primary, MLP) feature markers of pancreatic progenitor cells with progressive loss of insulin expression [29]. On the other hand, in rare cases, α-like NF-PanNETs may transdifferentiate by acquiring the ability to secrete insulin, usually presenting with a larger tumor size and aggressive phenotype [22].

Taken together, these studies reveal the presence of distinct NF-PanNET subgroups based on epigenetic signatures of endocrine differentiation, resembling either mature α- or β-cells.

Neuroendocrine Carcinomas

High-grade PanNENs consist of well-differentiated PanNET G3 and poorly differentiated neuroendocrine carcinoma (NEC). PanNET G3 share mutations with G1-G2 PanNET, including *MEN1*, *DAXX*, *ATRX*, *PTEN*, and *TSC2*, but they also have distinct ones such as *TP53*, while PanNECs are commonly mutated in *TP53*, *KRAS*, *BRAF*, and *PIK3CA/PTEN* [43–45]. The PanNEC mutational spectrum is similar to that of pancreatic ductal carcinoma, which may indicate a different cell of origin followed by transdifferentiation towards a neuroendocrine phenotype. Indeed, neuroendocrine transdifferentiation has been observed in ductal pancreatic adenocarcinoma in a MYC-dependent manner [46]. It is not uncommon to observe heterogeneous expression of cell markers of the exocrine lineage such as trypsin, MUC1, and CEA which may indicate cell plasticity and a possible clonal transdifferentiation [41] as well as a different cell of origin.

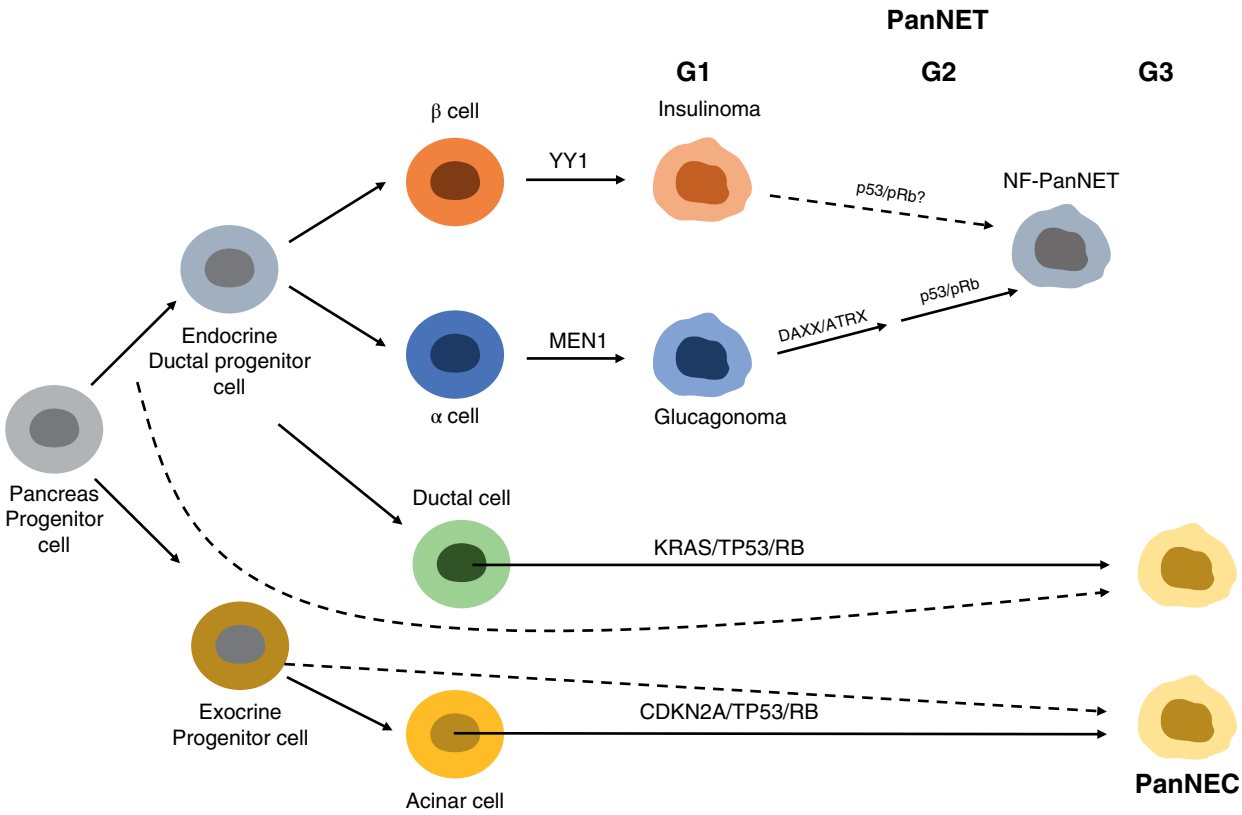

Figure 101.3 Proposed model of cell of origin with driving mutations of PanNEN.

A very recent study, based on mutational spectrum and epigenetic profiles, suggested that PanNECs include two different groups of tumors: PanNEC with acinar origin and PanNEC with ductal origin [14]. Ductal PanNECs present mainly mutation in *KRAS* and *TP53*, RB loss, and overexpression of duct lineage markers such as SPP1 and CFTR. Interestingly, expression of the transcription factors SOX2 and ASCL1 associated with increased chromatin accessibility was also found in this subtype. SOX2 is expressed in embryonic stem cells and neuronal progenitor cells, and has been shown to be important for neuroendocrine transdifferentiation in prostate cancer [47]. Acinar PanNECs instead present characteristic alterations in *CDKN2A* and in WNT signaling.

DNA methylation pattern accurately distinguishes PanNECs from all PanNENs, including G3 PanNETs [8]. Notably, PanNECs cluster together and show epigenetic similarities to acinar cells, rather than to endocrine cells. PanNECs showed consistent positivity for SOX9 and loss of expression of endocrine transcription factors ARX and PDX1. SOX9 is a crucial differentiation factor in pancreas development, which is expressed in a multipotent progenitor state and confined to ductal and centroacinar cells in the adult pancreas (see Fig. 101.1) [48,49]. These data together suggest that PanNECs originate from exocrine or stem cells. In contrast, well-differentiated PanNET G3 cluster with G1-G2 featuring endocrine α- and β-cells [8]. Interestingly, a subset of PanNET G3 also expresess SOX9 while retaining endocrine cells epigenetic similarity; thus NET-G3 may originate from endocrine cells and progressively lose cell differentiation via reexpression of progenitor markers.

Conclusion

In summary, converging evidence exists that insulinomas and a subset of low-grade nonfunctioning PanNET seem to arise from β- and α-cells of the pancreatic islets, respectively. They are driven by at least two different molecular pathways, driven by *YY1* and *MEN1* mutations. There is also evidence for a combined genetic (DAXX/ATRX) and epigenetic malignant evolution in the α-cell lineage towards more aggressive, epigenetically intermediate higher grade PanNET. In this scenario, a hormonal switch to insulin production also seems to occur in both human and mouse models. Possibly, a subset of well-differentiated PanNETs may also arise from endocrine precursor cells, and it can be anticipated that upcoming studies using single cell techniques will shed light on this question (see Fig. 101.3).

Interestingly, high-grade PanNEC could arise from ductal and/or acinar cells and shares some mutational patterns with the respective adenocarcinomas. Besides these general lines, observations from human tumors indicate potential additional plasticity: cases of mixed IMPN/NET with combined mutational background as well as NET-like differentiation on the infiltrative front of acinic cell carcinomas cannot fit into the current simplified model and is indicative of rare events of increased plasticity as well as microenvironmental factors influencing divergent differentiation.

Epidemiology of PanNEN

PanNEN represents 1–2% of all pancreatic tumors, and the annual prevalence is reported to be less than 1 per 100 000 individuals. According to the American SEER (Surveillance, Epidemiology and End Results) database, more than 60% of tumors registered between 1973 and 2004 were gastrointestinal NENs in which the ileum and rectum were sites of high incidence; 3.6% of these tumors were PanNENs [1]. However, according to the SEER study, the number of patients with this pathology has been increasing, with an annual incidence of 6.98 per 100 000 population in 2012, approximately seven times greater than the 1.09 per 100 000 population reported in 1973 [2]. Epidemiologic surveys for PanNEN were also conducted in Japan in 2005 and 2010 [3–5]. It was reported that approximately 2845 Japanese PanNEN patients were treated in 2005 whereas 3379 patients were treated in 2010; the number of PanNEN patients per 100 000 people was approximately 2.23 in 2005 and 2.69 in 2010. Moreover, the number of new patients per 100 000 people was estimated to be approximately 1.01 in 2005 and 1.27 in 2010. Hence, the number of NEN patients is definitely increasing in Japan as well.

Clinical Symptoms of PNET

As mentioned above, PanNET is broadly categorized into functional and nonfunctional entities. The clinical symptoms of functional PanNET are caused by excessive secretion of hormones. A Japanese epidemiologic study reports that approximately 35% of pancreatic NETs are functioning, indicating that most pancreatic NETs are nonfunctioning [5].

Functional PanNET

Three aspects must be taken into consideration when treating functional PanNET. First, multiple symptoms can be present because of the excessive levels of various hormones autonomously secreted by the tumors (Table 102.1) [6], possibly causing deterioration of the patient's quality of life or development of a life-threatening situation. Therefore, appropriate treatments for alleviating hormone symptoms are critical. Second, malignant functional NET may grow rapidly and can frequently metastasize to other organs during the course of the disease. Therefore, a multidisciplinary approach is of the utmost importance. Lastly, determination of multiple endocrine neoplasia type 1 (MEN 1) complications is also recommended [7,8].

Insulinoma

Insulinoma is characterized by hypoglycemic symptoms induced by excessive autonomous insulin secretion, and is categorized according to symptoms of the central nervous system and those of the autonomous nerve system. Central nervous system symptoms include headache, dizziness, disturbance of consciousness, and convulsions; they are sometimes mistaken for epilepsy or mental disease.

During hypoglycemic conditions, sympathicotonia can occur, followed by autonomic symptoms such as hunger, sweating, and tremors. As hypoglycemia improves upon consumption of food, a patient may tend to overeat,

Table 102.1 Symptoms and recommended tests for pancreatic functional neuroendocrine neoplasm [6]/Springer Nature/Public Domian CC BY 4.0.

Functional neuroendocrine neoplasm	Symptoms and findings	Differential diagnosis (presence diagnosis)
Insulinoma	Central nervous system symptoms: impaired consciousness (67–80%), abnormal vision (42–59%), amnesia (47%), personality changes (16–38%), epilepsy (16–17%), headache (7%)	Differentiating hypoglycemia: Whipple's triad, exogenous insulin, oral hypoglycemic agents, endogenous insulin dyssecretion, insulin autoimmune syndrome
	Autonomic symptoms: sweating (30–69%), malaise (28–56%), hyperphagia/obesity (14–50%), tremor (12–14%), palpitation (5–12%), anxiety (12%)	Definitive diagnosis: 72-hour fasting test, mixed-meal test, 48-hour fasting test + glucagon tolerance test
Gastrinoma	Peptic ulcers: duodenal bulb (75%), distal duodenum (14%), jejunum (11%)	Fasting serum gastrin measurement, gastric pH measurement, intravenous calcium injection test
	Abdominal pain, steatorrhea	(MEN1 differential diagnostics: blood calcium measurement, intact PTH measurement)
Glucagonoma	Glucose intolerance/diabetes (30–90%), weight loss (60–90%), necrotizing erythema migrans (55–90%), mucosal symptoms (30–40%), diarrhea (10–15%), anemia (30–90%), hypoaminoacidemia (30–100%), venous thrombosis, psychoneurotic symptoms	Plasma glucagon measurement, serum albumin measurement, amino acid fraction measurement
VIPoma	Profuse watery diarrhea, hypokalemia, fatigue, muscle weakness, shortness of breath, muscle cramps	Stool osmotic gap measurement
	Diarrhea: dark brown, odorless, low osmotic gap and secretory	Blood VIP cannot be measured in Japan
Somatostatinoma	Weight loss, abdominal pain, diabetes, cholelithiasis, steatorrhea, diarrhea, hypoacidity, anemia (often asymptomatic)	Blood somatostatin cannot be measured in Japan. Diagnosis by biopsy
Carcinoid syndrome	Skin flushing (without sweating), diarrhea, pellagra symptoms, psychiatric symptoms (i.e., confusion), heart failure (especially right heart failure), bronchospasm, intraabdominal fibrosis	Urinary 5-HIAA excretion measurement, intake of serotonin-containing foods and drugs

HIAA, hydroxy-indole acetic acid; MEN1, multiple endocrine neoplasia type 1; PTH, parathyroid hormone; VIP, vasoactive intestinal polypeptide.

resulting in weight gain or obesity. Persistence of this condition can lead to memory disturbances or the development of intellectual impairment; such cases are sometimes regarded as dementia or cerebrovascular disorders. Some patients may fall into a coma without presenting with any autonomic symptoms beforehand; therefore, a cautious approach is necessary. Meanwhile, fasting hypoglycemic events are not the primary symptoms in some insulinoma patients; instead, excessive insulin secretion is noted after glucose loading (i.e., after eating a meal).

Gastrinoma

Gastrinoma occurs primarily in the duodenum and pancreas, which ectopically secrete gastrin, resulting in the Zollinger–Ellison syndrome (ZES), which is due to marked hypersecretion of gastric acid causing severe gastroesophageal peptic disease. Abdominal pain, heartburn, nausea/vomiting, gastrointestinal bleeding, and gastrointestinal perforation may occur, and are symptoms of refractory ulcers or excessive gastric acid. Digestion-absorption disorder may also occur because gastric acid is not neutralized in the duodenum, and pancreatic digestive enzymes are inactivated. As a result, fatty diarrhea, weight loss, and other symptoms may be observed. ZES patients have two management problems that must be dealt with: control of acid hypersecretion and control of the gastrinoma, which is malignant in 60–90% of cases. Most gastrinomas are sporadic, but 20–25% of patients have it as part of the MEN 1 syndrome [9].

Glucagonoma

Glucagonoma characteristically presents with a specific dermatitis (necrolytic migratory erythema), which frequently occurs on the face, perineum, and limbs, causing itchiness and pain and exhibiting chronic healing/

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

recurrence cycles [9]. Excessive secretion of glucagon induces glucose intolerance, hypoaminoacidemia, hypoalbuminemia, weight loss, anemia, glossitis, angular cheilitis, venous thrombosis, mental symptoms, and other conditions. At presentation, glucagonoma is characterically large (>5 cm) and 50–80% of patients have advanced disease with metastatic liver lesions.

VIPoma

Secretion of electrolytes and water from the intestine is accelerated by autonomic excessive secretion of VIP (vasoactive intestinal polypeptide) from the tumor, resulting in severe watery diarrhea and hypokalemia as well as metabolic acidosis induced by massive excretion of bicarbonate ions. Owing to the secretin-like action of VIP, gastric acid becomes hypoacidic or anacidic. Various symptoms occur, including severe dehydration, weight loss, vasodilation-caused skin flushing, hypercalcemia caused by accelerated bone resorption, and glucose intolerance. Most patients with VIPomas present with advanced disease with liver metastases.

Somatostatinoma

Most cases of somatostatinoma in the literature do not have the clinical somatostatinoma syndrome, characterized by diabetes mellitus, gallbladder disease, diarrhea, weight loss, and steatorrhea, but are cases with no specific symptoms or found by chance that demonstrate immunohistochemical staining for somatostatin-like immunoreactivity.

Nonfunctional PanNET

No specific symptoms are present in patients with nonfunctional PanNET. As the tumor grows, nonspecific symptoms appear that include abdominal distension, abdominal pain, anorexia, and weight loss. Nonfunctional PanNET is often discovered following compression or invasion by the primary tumor or a distant metastasis. In the case of advanced liver metastasis, hepatic dysfunction and jaundice are observed.

According to the results of an epidemiologic study in Japan, approximately 22 months pass between the appearance of PanNET symptoms and disease diagnosis in symptomatic cases, on average [4,5]. While PanNET is not often encountered in actual clinical practice, it is important to consider it during differential diagnosis.

Diagnosis of PanNET

When repetitive hypoglycemic events or refractory gastrointestinal ulcers are investigated, differential diagnosis for functional PanNET is required, including insulinoma and gastrinoma. If functional PanNET is suspected on the basis of clinical symptoms, measurement of basal hormone levels in the blood and various loading tests are required to detect the presence of a hormone-producing tumor. If such a tumor is confirmed, its location should be accurately identified using imaging modalities; this is important for deciding the subsequent therapeutic strategy. Even if the presence of a tumor is first detected via imaging, as in the case of nonfunctional PanNET, the hormone-producing ability of the tumor as well as the presence or absence of metastasis should be investigated in detail. PanNET is often associated with MEN 1 so serum calcium and potassium levels should be determined upon initial examination to rule out excessive parathyroid hormone production. The following describes how to diagnose insulinoma and gastrinoma.

Diagnosis of Tumor Presence

Insulinoma

In the past, Whipple's triad (i.e., loss of consciousness on fasting combined with blood glucose levels <50 mg/dL, where symptoms improve upon consuming glucose) and Fajan's index for insulinoma (the ratio of plasma insulin concentration to fasting blood glucose >0.3) have been observed; however, false-negative findings should be ruled out. Testing such as a 72-hour fasting test and a mixed-meal test are recommended for definitive diagnosis [10], although there are recent reports of a 48-hour fasting test combined with a glucagon test [11].

Gastrinoma

The diagnosis of ZES should be suspected in any patient with peptic ulcer disease/gastroesophageal reflux disease (GERD) which is accompanied by diarrhea, personal or family history of endocrinopathies, or various laboratory findings (hypercalcemia, hypergastrinemia). Measurement of fasting serum gastrin and gastric acid secretion, and/or a 24-hour gastric pH monitoring test, are essential for diagnosis. It is important to inquire about the patient's medication history, as serum gastrin levels may increase owing to oral administration of proton pump inhibitors or H_2-blockers. For definitive diagnosis, a secretin or calcium stimulation test is useful, as gastrin secretion is increased by intravenous injection of secretin or calcium.

Localization Diagnosis

Many PanNETs are plethoric with inner uniformity; therefore, diagnosis is not difficult in typical cases. However, in atypical cases, it may be difficult to distinguish PanNET from a pancreatic ductal cancer or cystic

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

pancreatic tumor on differential diagnosis. Furthermore, insulinoma and gastrinoma are often small in diameter, and accurate localization is important for surgery. Therefore, various imaging modalities are employed during actual examination.

To determine the localization of PanNENs, it is recommended to consider and perform imaging such as ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), endoscopic ultrasonography (EUS), or somatostatin receptor scintigraphy (SRS) on a case-by-case basis. When performing histology, endoscopic ultrasound-guided fine needle aspiration (EUS-FNA) is recommended [12,13]. If microscopic insulinomas and gastrinomas cannot be localized by imaging, then a selective arterial secretagogue injection (SASI) test is useful [14,15].

Abdominal Ultrasonography

The more uniform the inside of tumor, the more likely the mass can be visualized on US. When the tumor is large, an irregular shape that reflects internal bleeding, necrosis, or cystic degeneration is sometimes observed. Abdominal US is easy to perform, and is the least invasive among imaging modalities. However, its diagnostic accuracy is low.

Abdominal Computed Tomography

When contrast medium is used, typical PanNETs are highly enhanced in the arterial phase (Fig. 102.1a). As contrast enhancement is weak in oligemic pancreatic ductal tumors, a CT image may be critical in distinguishing between PanNET and pancreatic ductal cancer. However, plethoric pancreatic tumors present the same contrast enhancement as PanNET, metastatic pancreatic tumor, and especially renal cancer; therefore, differential diagnosis should be carefully conducted. The diagnostic accuracy of CT is approximately 80% [16,17]. Further, liver metastases often show ringed enhancement (Fig. 102.1b).

Abdominal Magnetic Resonance Imaging

A T1-weighted MRI scan of a PanNET shows low intensity, whereas a T2-weighted scan shows high intensity (Fig. 102.2). On MRI, a tumor is visualized similarly to CT; however, the diagnostic accuracy of this method is approximately 70%, which is slightly lower than that of CT. On the other hand, for the detection of hepatic metastases from PanNET, enhanced MRI is more sensitive than enhanced CT (see Fig. 102.2) [17–19].

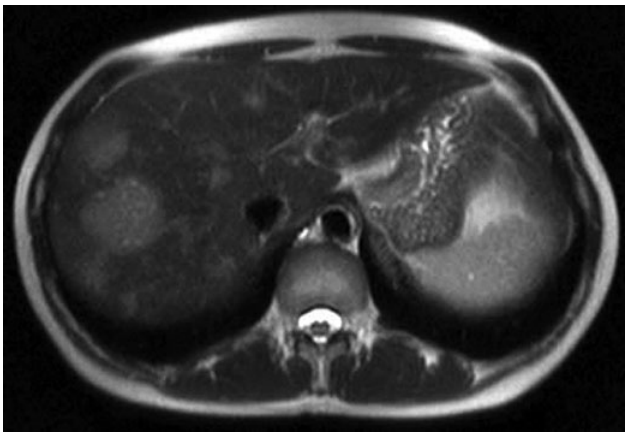

Figure 102.2 T2-weighted MRI findings of liver metastases in a patient with pancreatic nonfunctional neuroendocrine tumor.

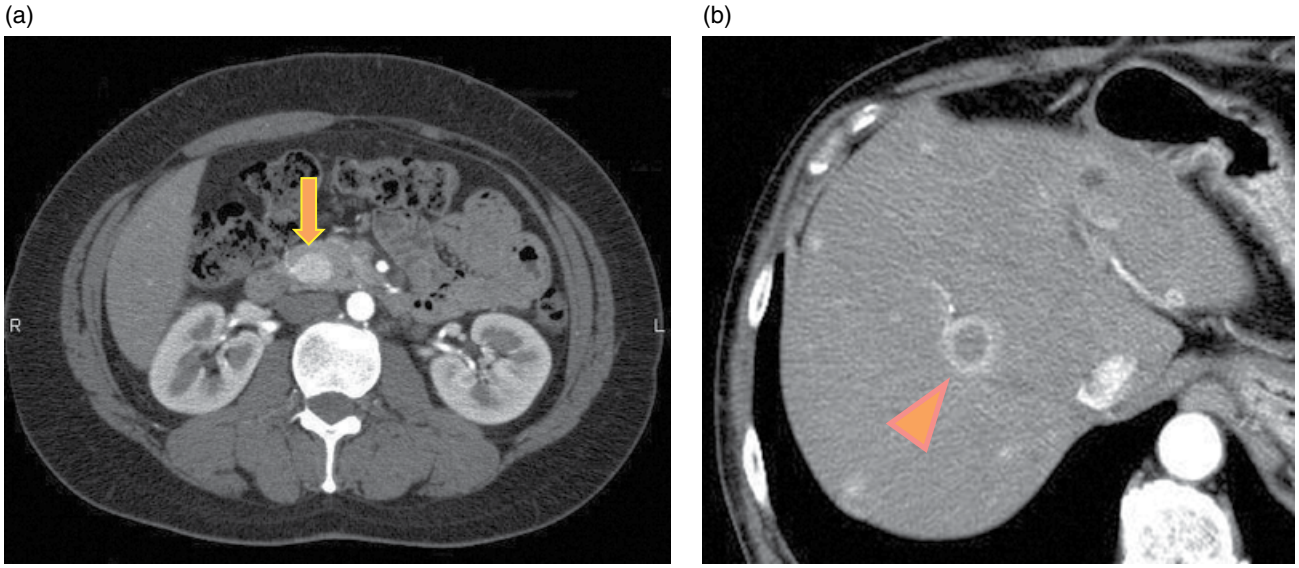

Figure 102.1 CT findings of nonfunctional neuroendocrine tumor in the pancreatic head lesion (a) and liver metastases (b).

Endoscopic Ultrasonography/Fine Needle Aspiration (Fig. 102.3)

PanNET is visualized on EUS as a hypoechoic mass with border regularity and inner uniformity. EUS can screen the entire pancreas and detect lesions <1 cm. With a diagnostic accuracy of approximately 80–95%, this method is superior to CT and MRI and is thus a very useful testing modality [20–22]. Furthermore, EUS-FNA has become an essential assessment for the qualitative diagnosis of pancreatic neoplasms.

The role of EUS-FNA in the diagnosis of PanNEN is two-fold. Its first role is to identify pancreatic neoplasms by EUS and to correctly diagnose PanNEN. Its second role is to diagnose the degree of malignancy according to the WHO classification using the Ki-67 index and mitotic index to aid the development of a treatment strategy once the condition has been diagnosed as PanNEN.

Selective Arterial Secretin/Calcium Injection Test

At the time of abdominal arteriography, a catheter is placed in the hepatic vein for secretin/calcium infusion into the feeding artery of each pancreatic region. The level of gastrin/insulin in the hepatic venous blood is then measured. The tumor's location is determined based on the increase of gastrin concentration (>2-fold). As the supply vessel for the tumor is identified, localization becomes possible for those tumors that are difficult to visualize by imaging modalities. This technique is especially useful as a preoperative test for gastrinoma and insulinoma [15,23].

Somatostatin Receptor Scintigraphy

Somatostatin receptor scintigraphy was approved for use in Japan in January 2016 and is beneficial for identifying the distribution of NET throughout the body. This method may be explained as follows: octreotide, a somatostatin analog containing pentetreotide labeled with radioactive indium (^{111}In), is intravenously administered. Subsequently, the labeled compound specifically binds with and accumulates in somatostain receptors (SSTR) to make imaging of NET possible. Concomitant use of single photon emission computed tomography (SPECT) is useful for improving the detection rate of lesions. Recently, ^{68}Ga-DOTATOC and ^{68}Ga-DOTATATE have been used for detecting rate of lesions [24]. For cases of PanNEN, SRS is used for the purposes of (i) diagnosis of localization and metastasis [25,26], (ii) confirmation of SSTR2 expression [27,28], and (iii) follow-up [29,30]. Here, one case is presented. The patient had a nonfunctioning PanNET with liver metastasis, and ^{111}In-SRS was observed to have accumulated in the primary focus in the pancreatic head, and liver metastatic focus was detected by CT (Figure 102.4a–d). However, by the use of ^{111}In-SRS, bone metastasis, which was not detected by CT, was found (Figure 102.4e) [12].

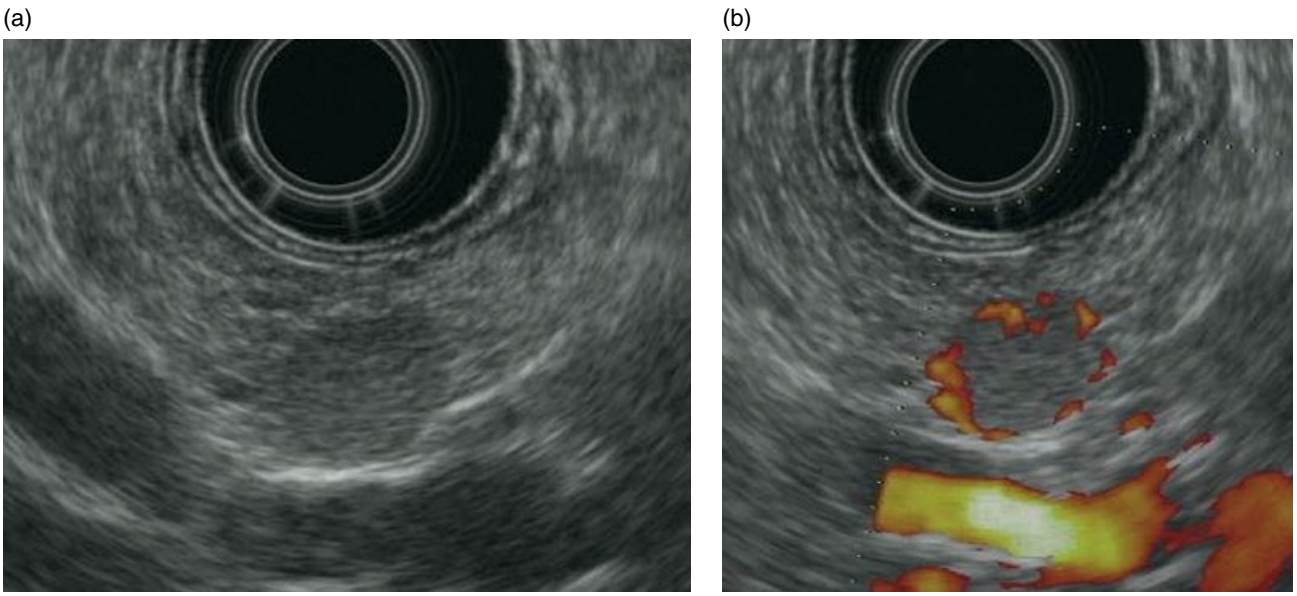

Figure 102.3 Endoscopic ultrasonography (EUS) findings of pancreatic neuroendocrine tumor. Typically, tumor is hypoechoic and homogeneous (a) and hypervascular on Doppler scanning (b).

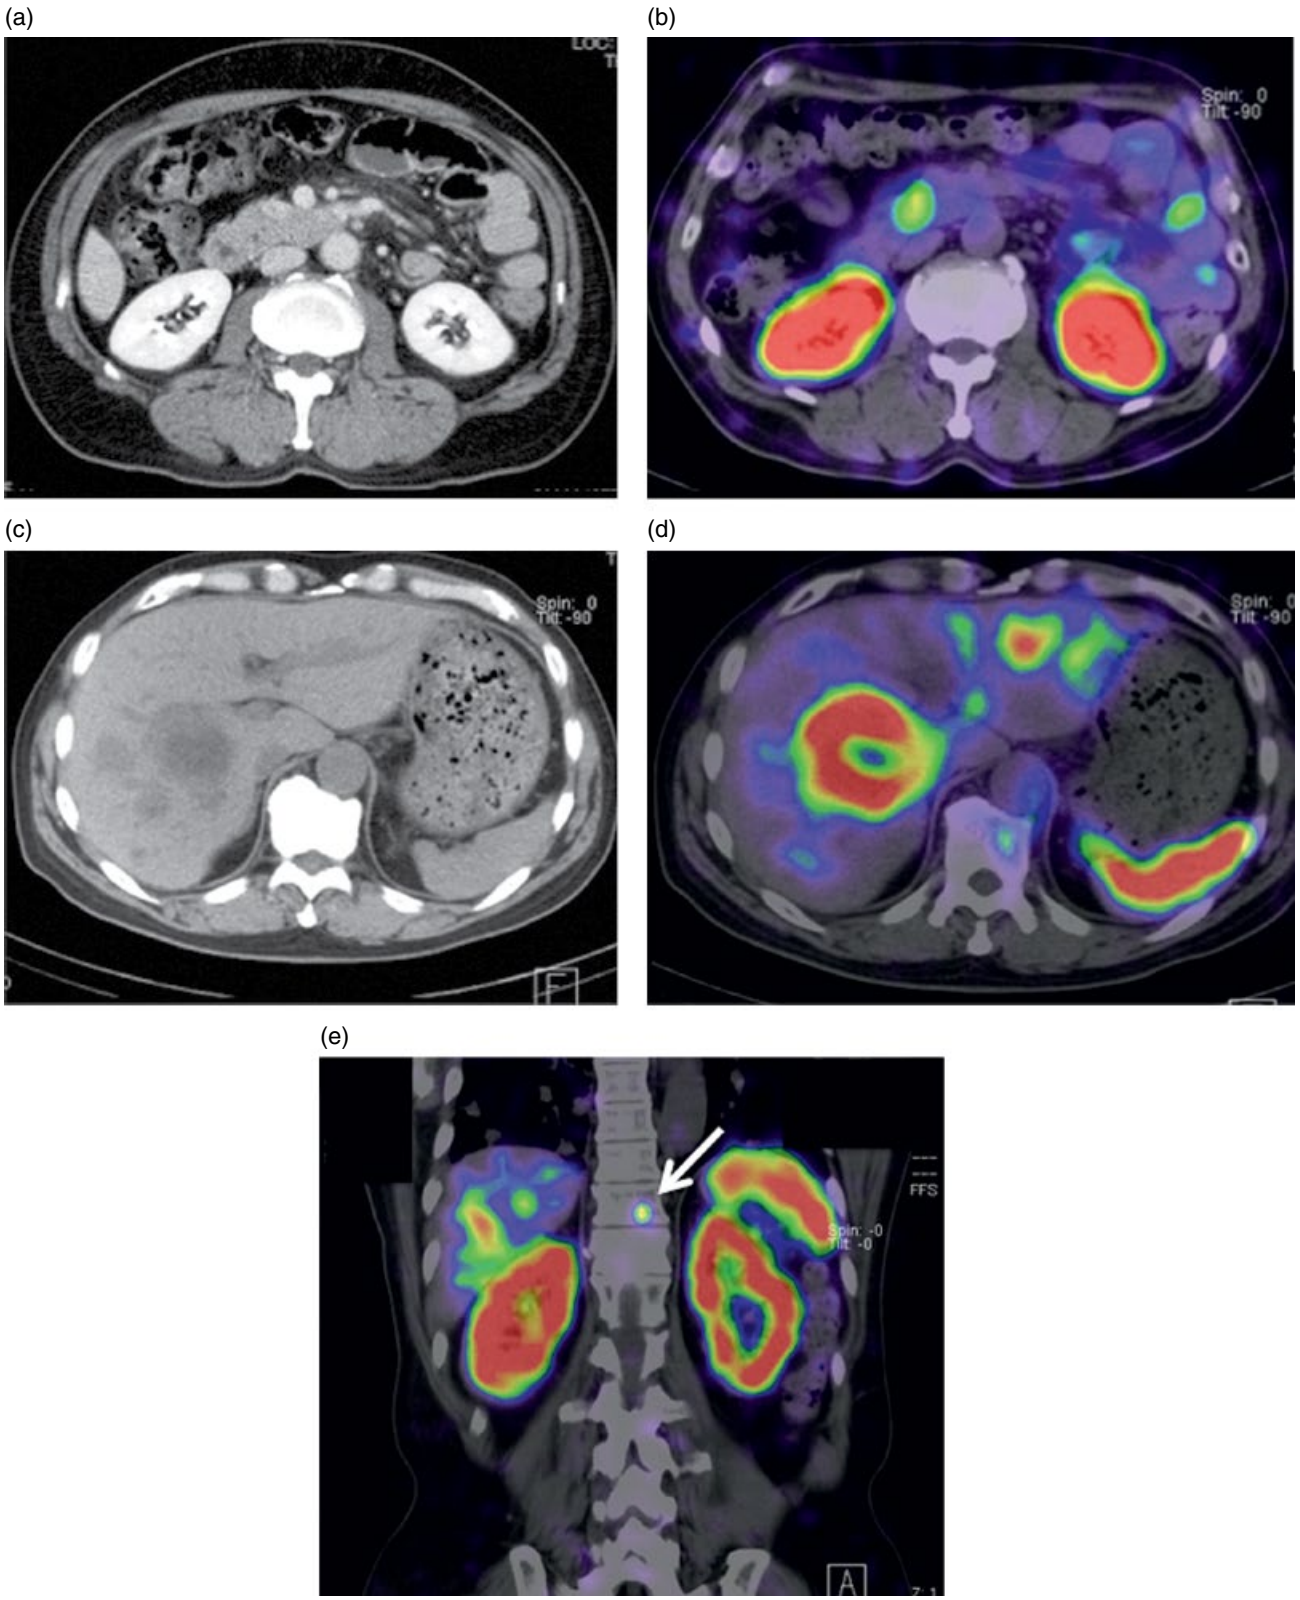

Figure 102.4 Somatostatin receptor scintigraphy (SRS) findings. The patient had a nonfunctioning pancreatic neuroendocrine tumor with liver metastasis. ^{111}In-SRS was observed to have accumulated in the primary focus in the pancreatic head, and liver metastatic focus was detected by CT (a–d). However, by the use of ^{111}In-SRS, bone metastasis, which was not detected by CT, was found (e).

Introduction

Pancreatic neuroendocrine tumors (pNETS) originate from neuroendocrine cells in the pancreatic islets and differ from other pancreatic neoplasms that originate from other pancreatic tissues. They often secrete a variety of molecules and overexpress somatostatin receptors (SSTR) on their cell surface. Traditionally, they have been divided into "nonfunctioning" and "functioning" pNETs.

In recent years, the rapid increase in pancreatic imaging has made the diagnosis of nonfunctioning pNETs as asymptomatic incidentalomas more frequent than functioning pNETs. These incidentalomas need to be distinguished from other pancreatic neoplasms for management and treatment decisions. In contrast, functioning pNETs pesent with clinical symptoms and signs and subsequently need imaging for localization and treatment.

The classic functioning pNETs are the insulinomas and glucagonomas which originate primarily from the pancreatic islets. Gastrinomas may originate from the duodenum and other parts of the gastrointestinal tract as well as the pancreas (see Chapter 102). These are rare, and many other hormones have since been reported from functional pNETs. They are even more rare, and often present with nonspecific symptoms. A multidisciplinary approach is best in the diagnosis and management of pNETS.

This chapter will describe the serum-based laboratory investigations followed by the various conventional and more recent pNET-specific radionuclide imaging investigations.

Serum-based Laboratory Investigations

Many pNETs, functioning or nonfunctioning, secrete "general NETs tumor markers" of which chromogranin A and neuron-specific enolase are the most useful [1]. Others include pancreatic polypeptide and chromogranin B, but these have lower specificity and sensitivity [1,2]. Finally, several centers have reported using "liquid biopsies," observing circulating tumor cells and serum DNA and RNA secreted by pNETS in unique patterns ("molecular signatures") as diagnostic and prognostic markers [3,4]. There is still a lack of standardization of the assays for these markers and thus there are difficulties in the interpretation of many of the laboratory-based investigations. Guidelines are updated frequently in Europe and North America.

Nonfunctioning pNETs frequently present as incidentalomas and do not secrete biologically active hormones giving rise to any symptoms or signs. However, many do secrete general NETs markers, and the most useful is still chromogranin A (ChA). Functioning pNETs present with classic syndromes to endocrinologists or gastroenterologists and need accurate diagnosis and assessment. Insulinomas and glucogonomas predominantly originate from pancreatic islets and metastasize elsewhere, but other pNETs secreting gastrin, serotonin, vasoactive intestinal polypeptide (VIP), SS, and many other hormones may originate from both pancreatic and extrapancreatic sites. Often, there may be incomplete or defective processing of the hormone and they may not be functionally active but still be identified in tissue immunochemistry, and be measurable in the serum in some

commercial assays. This may cause confusion as to whether they are "functioning" or not. Measurement of the relevant hormone, functioning or not, if elevated, remains useful for diagnostic and prognostic purposes.

All of these serum-based investigations should be carried out with the appropriate precautions and need to be interpreted carefully. Endocrine hormones may also be affected by their own dynamic regulation, food intake, and many commonly prescribed drugs.

Non-specific Biochemical Markers in pNETS

Many pNETS secrete molecules, which, if present, may be useful as biomarkers for diagnosis and prognosis [1,2]. These are useful in indicating a diagnosis of a pNET in incidentalomas of the pancreas, or where a nonfunctioning pNET is suspected. They include ChA, other chromogranins [5], neuron-specific enolase, pancreatic polypeptide, human chorionic gonadotrophin (hCG) subunits, synaptophysin, and pancreastatin (a derivative of ChA) [6]. Of these, only ChA has proved consistently useful as a marker, especially for monitoring for most functioning and nonfunctioning pNETs, except for insulinomas which are unusual in not secreting ChA. It is important to remember that ChA may also be elevated in other nonpancreatic neuroendocrine tumors, liver and kidney disease, and to a lesser and variable degree in atrophic gastritis and with the use of proton pump inhibitors. Neuron-specific enolase is useful mainly in poorly differentiated pNETs, and pancreatic polypeptide may be useful in nonfunctioning pNETs. However, all of these may be absent in many pNETs.

Insulinomas

Insulinomas are the most frequent functioning pNET and almost always originate in the pancreatic islets. Insulinomas are unlike other pNETS and rarely secrete ChA or overexpress SST receptors. Insulinomas may be sporadic or be associated with multiple endocrine neoplasia 1 (MEN 1) where they present as multiple pancreatic tumors (see Chapter 104 – MEN chapter). Diagnosis of an insulinoma requires the clear demonstration of inappropriately elevated serum insulin concentrations in the presence of hypoglycemia, and exclusion of other causes. They are usually benign at the time of diagnosis.

The gold standard for diagnosis is the supervised prolonged fast (72 hours) with regular venous blood sampling every 4–6 hours for glucose, insulin, and c-peptide. The fast is terminated if there is hypoglycemia (glucose <55 mg/dL or <3.0 mmol/L) with symptoms and signs. The presence of inappropriately elevated serum insulin and c-peptide concentrations (even within the normal range) during hypoglycemia is diagnostic, but sulphonylurea abuse has to be excluded [7]. Absolute cut-off values have to be interpreted within the context of the laboratory, as both insulin and c-peptide assays are not standardized. A 48-hour or 24-hour fast, followed by vigorous exercise, with or without the aid of continuous glucose monitoring, has been reported to be nearly as good in making a conclusive diagnosis [8]. With the improvement in imaging, provocative tests with infusion of arginine, calcium, and glucagon are no longer recommended.

An elevated insulin concentration with a low c-peptide value indicates surreptitious exogenous insulin administration. An elevated plasma proinsulin to insulin ratio, if available, supports the diagnosis of an insulinoma. Urine or plasma sulphonyurea should be measured, as both insulin and c-peptide are elevated in patients taking these drugs surreptitiously [7]. In ethnic East Asians, anti-insulin autoantibodies should also be measured to exclude insulin autoimmune syndrome [7,9]. Care should also be taken in the interpretation of elevated insulin levels values and hypoglycemia if there has been bariatric surgery within recent years [10,11].

Imaging investigations should proceed only after establishing a laboratory diagnosis (see below). If available, exendin-based positron emission tomography (PET) scanning would be valuable in localization prior to surgery (Fig. 103.1) [11,12].

Gastrinomas

Gastrin-secreting pNETS occur sporadically and in association with MEN 1 (1 in 4 in some series). They are often multiple and malignant and are present mostly in the duodenum as well as the pancreas at diagnosis. The hypergastrinemia causes severe gastric hyperacidity, with abdominal pain, increased gut motility and diarrhea, giving the classic Zolinger–Ellison syndrome. Many patients are already on acid suppression drugs, and the proton pump inhibitors (PPIs) are effective for the symptoms. However, all acid suppression medications will cause hypergastrinemia and need to be stopped before investigations.

The diagnosis of a gastrinoma requires stopping preexisting acid suppression drugs (seven days or longer for proton-pump inhibitors [PPIs], two days for others) and measurement of fasting serum gastrin. Fasting serum gastrin is usually markedly elevated [1]. However, difficulties arise because of the lack of standardization of gastrin assays and the absence of normal population ranges. Elevated fasting serum gastrin may also be present in chronic kidney disease, atrophic gastritis, and short bowel syndrome. Finally, several molecular forms of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 103.1 Flow chart for investigations in suspected pNETs.

gastrin may be secreted which may or may not be accurately measured by many of the available commercial assays [13]. Thus, care has to be taken in the preparation of the patient before taking measurements, and in the interpretation of the results. Many patients with gastrinomas are *H. pylori* negative, and the presence of multiple peptic ulcers in such patients should raise the index of suspicion.

The secretin stimulation test has been reported to be useful, especially when hyperacidity symptoms are too severe to permit withdrawal of acid suppression drugs. A 2 U/kg bolus of secretin is administered intravenously after an overnight fast and serum gastrin is measured at 0, 2, 5, 10, and 15 minutes. An increase in serum gastrin of >200 pg/mL is considered diagnostic. However, false-positive results may still occur and care has to be taken in the interpretation of these tests [1,14].

Imaging studies should proceed if there is clear suspicion of a gastrinoma based upon the presence of severe hyperacidity or multiple peptic ulcers on endoscopy. Somatostatin-based PET/computed tomography (CT) may be necessary if other imaging modalities are negative.

Glucagonomas

Glucagon-secreting pNETs are very rare and almost always originate from the pancreas. They are usually sporadic but may rarely be associated with MEN 1. The classic clinical syndrome of diarrhea, weight loss, hyperglycemia, and necrolytic migratory erythematous rash [15] is usually recognized late, when the tumor is often large, with liver and other metastases already present (see Chapter 102). Mild anemia and recurrent venous thromboembolism are common. The grossly elevated concentrations of fasting serum glucagon, and imaging findings, will give a clear diagnosis. However, glucagon measurements in the absence of clinical signs are difficult to interpret.

Secretion of glucagon is affected by many factors, and many smaller glucagon-like molecules, including glucagon-like peptide-1 (GLP-1), are present in the blood and may give falsely elevated results [16]. Elevated fasting glucagonemia may be found in liver cirrhosis, chronic kidney disease, acromegaly, and hypercortisolism.

A conventional CT is usually sufficient to identify the tumor because of the late presentation and diagnosis.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Vasoactive Intestinal Peptide (VIPomas)

VIPomas are rare and sporadic and more than 90% are located in the pancreas at diagnosis [17]. Like gastrinomas and glucagonomas, they are diagnosed late, often with metastases at presentation. The classic presentation is that of severe watery diarrhea, hypokalemia, hypochlorhydria and occasionally facial flushing (Verner–Morrison syndrome or the pancreatic cholera syndrome). Serum VIP concentration is grossly elevated and is usually diagnostic. In the early stages, VIP secretion may be intermittent and should be measured during episodes of watery diarrhea. Elevated VIP concentrations may also be found in chronic kidney disease, short bowel syndrome, and radiation enteritis. Diagnosis is more difficult in countries with endemic cholera but infective causes are usually milder and self-limiting.

Imaging studies with SSTR radionuclides may be helpful in the detection of this rare pNET.

ACTH-secreting pNETs

The diagnosis of Cushing syndrome due to ectopic adrenocorticotrophic hormone (ACTH) secretion is often difficult and usually presents as a diagnostic challenge to the endocrinologist [18]. A pNET may be one of the rare possibilities. The initial screening test for hypercortisolemia is the 1 mg overnight dexamethasone test; an adequate suppression of serum cortisol excludes hypercortisolemia in most cases. In the event of uncertainty, hypercortisolemia should be confirmed with a formal three-day 2 mg low-dose dexamethasone suppression test. The plasma ACTH should then be measured to distinguish between an adrenal cause and an ACTH-dependent hypercortisol state. If the ACTH concentration is inappropriately elevated, then further investigations are necessary to distinguish between a pituitary tumor and an ectopic ACTH-secreting tumor. This may include a corticotrophin hormone (CRH) test, inferior petrosal sinus sampling, or a combination of the two.

In ectopic ACTH-dependent Cushing syndrome, imaging and localization studies for the extrapituitary NET will begin with the pancreas, lung, and thymus. Imaging of the pancreas with fine-cut CT may reveal an ACTH-secreting pNET. Rarely, pNETS may secrete CRH. Measurements for serum CRH are not widely available, and interpretation is difficult.

Imaging with SSTR radionuclides is useful if conventional CT or MRI do not reveal a tumor.

Other Functional pNETS (Somatostatin, Serotonin, Ghrelin, Growth Hormone-releasing Hormone, Parathyroid Hormone, PTH-related Peptide)

There are increasing reports of pNETS secreting other functioning hormones, usually as case reports or small series. The hormones include somatostatin (SST), serotonin, ghrelin, growth hormone-releasing hormone (GHRH), parathyroid hormone (PTH), PTH-related peptide (PTH-RP), renin, and erythropoietin. Many of these hormones are not routinely measured and, moreover, measurements are not standardized or readily available. If the pNET is diagnosed as a small incidentaloma, the secretions may not have caused severe enough clinical signs and symptoms, and thus it may be treated without measurement of these hormones. Many of the secretions are episodic, and levels may be difficult to interpret. The existing guidelines do not recommend routine measurement of these hormones in the absence of symptoms and signs. However, it is important to be aware of the possibility of rare secretions from pNETs and thus reduce the delay in diagnosis [19].

Somatostatin-secreting pNETs are thought to be very rare and sporadic, usually arising from the pancreas but may also be found in the duodenum. Symptoms are usually mild and nonspecific and include hyperglycemia, weight loss, abdominal pain, gallbladder stasis, and diarrhea [20]. Liver and other metastases are usually present at diagnosis. Elevated SST levels are diagnostic but like other rarely measured hormones, available assays vary considerably in characteristics and ranges. Elevated serum SST may also be found in medullary thyroid tumors, small cell lung tumors, pheochromocytomas, and paragangliomas.

Serotonin (5 hydroxytryptamine, 5-HT)-secreting NETs originating in the pancreas are very rare, as these classic "carcinoid tumors" are more frequent in the hindgut and other locations [21]. When found as a pNET, they are usually large and present with metastases at diagnosis. The 5-HT metabolite, 5-hydroxyindoleacetic acid (5-HIAA), measured in a 24-hour urine collection sample, is still the investigation of choice and is elevated in most patients with the classic symptoms of facial flushing, diarrhea, and right heart failure.

Ghrelin-secreting and GHRH-secreting NETs orginate from the pancreas and other gastrointestinal tract tissues. They are very rare, and are usually sporadic or associated with MEN 1. Ghrelin and GHRH cause classic acromegaly, which presents to the endocrinologist. There should be suspicion of an ectopic extrapituitary

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

location if there is elevated GH in the presence of a generally enlarged pituitary gland on MRI without a defined pituitary adenoma. Ghrelin and GHRH assays are not standardized and some have reported elevated ghrelin without any symptoms and signs of acromegaly [22].

Many other functioning pNETS have been reported as case reports, and include the following: PTH- and PTH-RP-secreting pNETS causing hypercalcemia, renin-secreting pNETS causing hypertension, erythropoietin (EPO)-secreting pNETS causing polycythemia, and calcitonin, cholecystokinin and neurotensin all usually presenting with nonspecific symptoms. It is likely that there will be more reports when more assays become available and our understanding of the pathophysiology of these various hormone-secreting pNETS improves.

Somatostatin analogue radionuclides have been very useful in the diagnosis and localization of these tumors but are not often necessary as these tumors are often large enough at presentation to be diagnosed with conventional CT or magnetic resonance imaging (MRI).

Serum RNA and DNA Measurements in pNETS

Recent advances in measurement of circulating serum DNA, RNA, and circulating tumur cells have led to studies of their usefulness in the diagnosis and management of pNETs. Studies on serum DNA, together with fresh tissue from patients with NETs, have been reported to identify DNA patterns and secretion into the circulation. Similarly, serum RNAs, including microRNAs (miRNA) and long noncoding RNAs (lcRNA), have been measured in various pNETs. These various patterns ("signatures") have been reported as potentially useful in distinguishing NETs from other pancreatic tumors. A commercial assay has become available and has been reported to be better than ChA [23,24] as a biomarker for NETs.

Table 103.1 gives a list of the more common functional pNETS and summarizes the useful laboratory and imaging investigations.

Imaging

Asymptomatic pancreatic "incidentalomas" are increasingly being diagnosed as a result of a general increase in frequency of abdominal imaging and greater awareness of these lesions among radiologists. Various features of these "incidentalomas" suggest different possible diagnoses, with isolated nonfunctioning pNETs as one of them. Although some features on imaging may suggest a pNET, a tissue diagnosis is needed for management decisions. For classic functioning pNET with suggestive symptoms and signs and biochemical evidence, ultrasound, conventional CT, MRI, and radionuclide scans all play a part in the localization and assessment of the tumor.

There has been rapid progress in many of the investigations for pNETs with better dynamic enhanced CT and MRI techniques, and novel radioisotope linked ligands and molecules for nuclear imaging. Radionuclide imaging based on the unique specific expression of the SSTR and/or unique metabolic features is particularly important in the detection and investigation of pNETs. The introduction of the copper-64 marker Cu-64, linked to somatostatin analogues, has improved PET images further [25].

Conventional CT and MRI

Conventional CT and MRI are useful and adequate for the diagnosis and localization of most functioning larger pNETS (around 1 cm in diameter or more). Recent developments in multiphase contrast-enhanced CT and dynamic MRI have reported good results for earlier detection and characterization of smaller and nonfunctioning pNETs [19,20], and for staging [26]. Pancreatic NETS are usually densely hypervascular and therefore appear as well-circumscribed masses with early strong enhancement from the arterial to pancreatic phase. Diffusion-weighted MRI (DWI) has also been reported to be useful, alone or in conjunction with SST-based radionuclide imaging, in the detection of some pNETs [27,28].

Pancreatic NETs usually appear as low intensity images on T1 and high intensity on T2, with clear gadolinium enhancement. These findings may be adequate in the localization of many pNETS, especially when sophisticated and expensive specialized radionuclide SSRT and other PET/CT imaging facilities are unavailable. However, despite all the advancements, conventional CT and MRI are less able to identify the full extent of metastases.

Conventional PET Scans

Conventional 18-fluorodeoxyglucose (^{18}FDG) PET scans (including PET/CT) identify tumor cells with high glucose utilization, and identify aggressive tumors with higher metabolic rates. More indolent tumors, like many pNETs, are not identified using ^{18}FDG scans. They are therefore not as helpful in the investigation of pNETS as in other pancreatic tumors.

To identify pNETs, other radionuclides have been studied actively – those based on the specific metabolic

Table 103.1 More common functional pNETS and useful laboratory and imaging investigations.

	Differential diagnosis	Pancreatic origin (versus other locations)	Laboratory investigations	Imaging investigations	Other special investigation
Suspected functioning pNET					
Insulinoma	Factitious; autoimmune disease	>90%	Prolonged fast with glucose, insulin and c-peptide measurements Chromogranin A often negative	Endoscopic ultrasound	Selective intraarteriolar calcium infusion (used in some centers still) GLP-1 analogue (exenatide) radionuclide scan
Gastrinoma	Acid-suppressing medications (proton pump inhibitors)	<50% Often in duodenum	Fasting serum gastrin; secretin test – if available; chromogranin A	Endoscopy/EUS MRI	SSTR imaging (preferentially gallium labeled)
Glucagonoma	Secondary diabetes from other causes	>90%	Serum glucagon Chromogranin A	Conventional imaging	Conventional CT/MRI usually adequate Rarely SSTR imaging
VIPoma	Other causes of hypokalemic diarrhea	>90%. May be in other GIT sites	Serum VIP Chromogranin A	Conventional imaging	SSTR imaging
Somatostatinoma		<50% Other sites include duodenum and other foregut sites	Serum somatostatin Chromogranin A		Unknown. SSTR imaging may be useful
ACTH	Nonpancreatic ectopic ACTH tumor	<10% More often in lung and other sites	Dexamethasone suppression test CRH stimulation test	Endoscopic US and conventional imaging	Exclusion of pituitary Cushing syndrome SSTR imaging
Ghrelin, GHRH	Nonpituitary acromegaly with high GH	<5% Most often in pituitary	Ghrelin, GHRH	Endoscopic US and conventional imaging	Exclusion of pituitary acromegaly SSTR imaging
Others – PTH-RP Renin Erythropoietin	Other causes of symptoms and signs	<50% Can be any GIT or other site	Chromogranin A	Endoscopic US and conventional imaging	Unknown. SSTR imaging may be useful
Serotonin	Classic "carcinoid" syndrome	<10% More often in lower GIT and lung	24-hour urine 5-HIAA Chromogranin A	Endoscopic US and conventional imaging	SSTR imaging
Nonfunctioning pNET			Chromogranin A, neuron-specific enolase, human pancreatic polypeptide, serum DNA signatures	Dynamic CT or MRI	SSTR imaging

PET-CT with SSTR radionuclides: Ga^{68} DOTA-TOC, DOTA-TATE and DOTA-NOC, or Cu^{64} DOTA-TATE.
Non-SSTR radionuclides are not widely available and include PET/CT with Ga^{68} DOTA-exendin 4, PET with Fl^{18} DOPAMINE.
ACTH, adrenocorticotrophic hormone; CRH, corticotrophin-releasing hormone; CT, computed tomography; EUS, endoscopic ultrasound; GH, growth hormone; GHRH, growth hormone-releasing hormone; GIT, gastrointestinal tract; GLP, glucagon-like peptide; HIAA, hydroxy-indole acetic acid; MRI, magnetic resonance imaging; PTH-RP, parathyroid hormone-related peptide; SSTR, somatostatin receptor; VIP, vasoactive intestinal polypeptide.

characteristics (and those based on cell surface receptor expression, see below) of pancreatic islet cells. Dopamine is a major metabolite of many NETs and dopamine-based radionuclide studies have been reported using 18-fluorodopamine (^{18}F-Dopa), 11C-L-dopamine (^{11}C-L-DOPA), and 11C-5-hydroxytryptophan (^{11}C-5-HTP) for serotonin pNETs [29]. However, these have been reported to be of use only in pNETs with negative or minimal SSTR expression and the development of the SST radionuclides has diminished their potential.

Somatostatin and Other Peptide Receptor-based Radionuclide Imaging

Most differentiated functioning (except insulinomas) and nonfunctioning pNETS overexpress cell surface SSTRs. This has led to the development of radionuclides based on somatostatin analogues. Of the five SSTR subtypes, pNETs usually overexpress SSTR subtype 2. The main radionuclide used is octreotide, which selects for SSTR-2, and has a longer half-life than native somatostatin. Octreotide was initially used with the tracers iodine I-123 and indium In-111 (commercialised as Octreoscan®) and subsequently technetium Tc-99m. However, these have been superseded by PET/CT scanning with gallium Ga-68 linked to octreotide analogues via the chelating molecule DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid).

Three main DOTA compounds have been extensively studied and compared in large numbers of pNETs: DOTA-TOC (DOTA-Tyr-octreotide), DOTA-TATE (DOTA-Tyr-octreotate), and DOTA-NOC (DOTA-Nal-octreotide). They are all able to identify both functioning and nonfunctioning pNETs and their metastases with a high specificity and sensitivity (>80%). The differences reported in different pNETs of differing histologic stages are minor and may be the result of different study populations [29]. More recently, copper-64 has been used instead of gallium-68 as the radioactive tracer, linked to octreotate with the chelating molecules DOTA or with NODAGA (1,4,7-triazacyclononane,1-glutaric acid) (Cu-64-NODAGA) with improved imaging qualities, lower costs, and greater flexibility in the timings of injections and imaging and thus better results [30,31].

Other Radionuclide Scans

Other peptide receptors have been identified in pNETS and attempts have been made to utilize these for imaging (and therapy) in the less common pNETs with less overexpression of SSTR. These would have the greatest potential in insulinomas where the GLP-1 receptor and the glucose-dependent insulinotropic peptide (GIP) receptor are expressed in abundance. The GLP-1 analogue exendin-4 linked to Ga68-DOTA has shown promising results [11,12] but its usefulness will remain restricted to insulinoma and its metastases. Other peptide receptors are being actively investigated at present and may have potential in pancreatic and other NETs, including cholecystokinin-2/gastrin, gastrin-releasing peptide, neuropeptide-Y, and bombesin [32].

A multitargeted approach using a cocktail of three different radioligand peptide receptors at the same time, targeting the SSTR, GLP-1 R and GIP R, suggested better results than single radioligand imaging [33]. While this approach will save time, the costs will invariably be much higher. Moreover, interpretation may be difficult as normal tissues have different levels of expression of these peptide receptors, and thus false-positive and -negative rates will have to be confirmed in other centers. In addition, in peptide receptor radionuclide therapy (PRRT – see Chapter XX), information is necessary on the relative abundance of single receptor types, as the therapeutic doses of the therapeutic radioisotope, most commonly lutetium-177 or yttrium-90 (Y90), are bound to single analogues. This information will be lost if a cocktail of radionuclides is utilized for imaging.

Instrumental and Invasive Investigations

Even when biomarkers and imaging characteristics are indicative of a pNET, small nonfunctioning pancreatic incidentalomas often still require instrumental and invasive investigations to obtain tissue biopsies for accurate diagnosis and grading of the tumor. Endoscopic US combined with guided fine needle aspiration cytology and/or core biopsy will therefore remain the gold standard for accurate diagnosis in small nonfunctioning pNETs. This may be dependent on the availability of expertise and experience.

Apart from asymptomatic incidentalomas, some small functioning pNETs may require invasive investigations to locate the tumor within the pancreas, for tissue diagnosis and grading, and to diagnose multiple tumors. Despite all the advances in MRI and radionuclide imaging, endoscopic US of the pancreas may still have some advantages [34], and in combination with radiofrequency ablation will potentially be very useful in treatment of small pNETs or other pancreatic tumors. This would be especially useful in small biochemically proven insulinomas or VIPomas. Both insulinomas and VIPomas are almost always confined to the pancreas. Insulinomas rarely secrete ChA and are not detectable on SSTR radionuclide imaging. If all these investigations still are unable to localize a biochemically confirmed insulinoma, progressive partial pancreatectomy may be necessary,

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. which may reveal single or multiple tiny insulinomas or diffuse nesidioblastosis.

Conclusion

Pancreatic NETs are rare and heterogeneous tumors. Biochemical investigations are essential, but interpretation may be difficult at times because of the use of nonstandardized assays. Advances have been made in conventional CT and MRI and rapid progress is being made in the development of new radionuclide tracers and chelators. The unique overexpression of SSTR in most pNETs has made this an essential modality for diagnosis, staging, and therapy. Advances in endoscopic ultrasound have been refined, and endocscopic US-guided biopsy of pNETS has facilitated tissue diagnosis and tumor grading and therapy.

Pancreatic Neuroendocrine Tumors in Multiple Neoplasia Syndromes

Anja Rinke and Thomas Matthias Gress

Department of Internal Medicine, Division of Gastroenterology and Endocrinology, UKGM Marburg, Marburg, Germany

Introduction

Neuroendocrine tumors, including pancreatic neuroendocrine tumors (PanNETs), are on the rise and, probably owing to improved imaging techniques and better awareness, especially localized disease is more often diagnosed [1]. Although most of these tumors are sporadic, in about 17% of PanNETs there is a hereditary background with multiple endocrine neoplasia type 1 (MEN 1) being the most relevant family cancer syndrome for PanNETs [2]. Early diagnosis of the hereditary syndrome is of diagnostic and therapeutic relevance for the patient and their kindreds. Diagnostic procedures, follow-up, and treatment should be managed by a multidisciplinary team with experience in the management of MEN 1 [3]

MEN 1 should always be suspected in patients with PanNETs with multiple lesions, a positive family history, a second MEN 1 typical manifestation such as hyperparathyroidism or pituitary tumor, in patients with insulinoma in young age (<30 years) or in cases of gastrinoma/Zollinger–Ellison syndrome (ZES) even in the absence of a positive family history. In addition to the classic "three-P triad" of **p**arathyroid tumor (90–100% of cases), **p**ituitary tumor (20–60%), and **p**ancreatic tumor (60–80%), patients with MEN 1 may also develop adrenocortical tumors, lipomas, carcinoid tumors, including thymic, gastric, and lung carcinoids, facial angiofibromas, collagenomas, and meningiomas and may also have an increased risk for other nonendocrine malignant tumors such as lymphoma, myeloma, melanoma, renal cell cancer, ovarian tumors, breast cancer, and sarcoma [4,5]. This chapter focuses on the management of PanNETs in MEN 1.

Epidemiology

With an estimated prevalence of 0.02–0.2 per 1000 inhabitants, MEN 1 is one of the most common familial cancer syndromes; in an old autopsy study, the reported incidence was 0.25% [6–8]. Duodenopancreatic neuroendocrine tumors are the second most frequent manifestation of MEN 1. Older studies probably underestimated the prevalence of PanNETs in MEN 1 syndrome and with more sensitive diagnostic tools and regular screening, about 90% of patients are found to develop PanNETs at the age of 70 [9]. PanNETs have an earlier age of onset in patients with MEN 1 than in patients without MEN 1. These tumors are typically multiple and can present with hormone syndromes or be nonfunctioning [10,11]. The most common hormone-active duodenopancreatic tumors are gastrinomas, followed by insulinomas, whereas vasoactive intestinal peptide-releasing tumors (VIPomas) and glucagonomas are rare. Approximately 20–30% of all patients with ZES will have MEN 1 [3,12].

Genetics

MEN 1 is an autosomal dominant inherited syndrome with high penetrance; nearly 100% of persons with germline MEN 1 mutation will develop symptoms of MEN 1 during life. In 1988, the *MEN1* gene locus was first mapped to the long arm of chromosome 11 (11q13) [13] and in 1997 the gene was identified and cloned [14]. It acts as a tumor suppressor gene and codes for the 610 amino acid protein menin, which is involved in transcription regulation, genome stability, and proliferation [3,14].

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

In about 10% of MEN 1 cases, the germline mutation arises *de novo* and the family history is negative [3].

More than 1300 inactivating mutations involving all locations of the gene have been identified so far and in about 90% of clinically diagnosed MEN 1 cases, the mutation in the *MEN1* gene can be detected [3]. About 70% of the mutations are nonsense and frameshift mutations, resulting in truncation of the protein. Although there is no clear genotype–phenotype correlation and even in one family the manifestations may vary [15,16], a recent publication described an increased prevalence of PanNETs and increased risk of metastasis in patients harboring an exon 2 mutation [17]. The diversity of mutations makes mutational analysis in MEN 1 difficult and complete sequencing of the whole gene is necessary. In contrast, if the mutation of an index case in the family is known, family members only have to be analyzed to determine whether the known mutation is present or absent.

Diagnosis

Three diagnostic criteria for MEN 1 exist, each individually establishing the diagnosis of MEN1 [3,8].

- Genetic: identification of a germline MEN 1 mutation in the individual, or
- Familial: diagnosis of a MEN-associated tumor in a person who has a first-degree relative with known MEN 1, or
- Clinical: occurrence of two or more primary MEN 1-associated endocrine tumors.

The diagnosis of a PanNET may result either from symptoms (e.g., hypoglcycemia in a patient with insulinoma) or from biochemical (elevated levels of pancreatic polypeptide, gastrin, insulin, glucagon, vasoactive intestinal polypeptide [VIP]) or morphologic screening (identification of pancreatic lesions in computed tomography [CT], magnetic resonance imaging [MRI], endoscopic ultrasound, somatostatin receptor imaging).

In a patient with MEN 1 syndrome, initially at least annual biochemical and morphologic screening for PanNET is recommended [3] but the frequency of imaging should be individually adapted and intervals may be lengthened once it can be demonstrated that there is no rapid growth [8]. Endoscopic ultrasound (EUS) is more sensitive for detection and follow-up of small pancreatic lesions than CT or MRI [18,19] and can be combined with fine needle biopsy. MRI is a recommended alternative if EUS by an expert is not available [8].

In patients with gastrinoma, upper gastrointestinal endoscopy is indicated. Typically, gastrinomas in MEN 1 are small, multiple, and located in the duodenum, where the sensitivity of EUS is inferior compared with pancreatic lesions. In some publications and the recent guideline, a role for [^{68}Ga] DOTA-TOC (DOTA, 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid; DOTA-TOC, DOTA-Tyr-octreotide) positron emission tomography (PET)/CT or DOTA-TATE (DOTA-Tyr-octreotate) PET/CT for exclusion of small metastases in patients with MEN 1 and PanNET has been suggested (Fig. 104.1) [8,20,21]. For insulinomas, somatostatin receptor-based imaging is less sensitive but glucagon-like peptide 1 receptor (GLP-1R)-based PET/CT has been

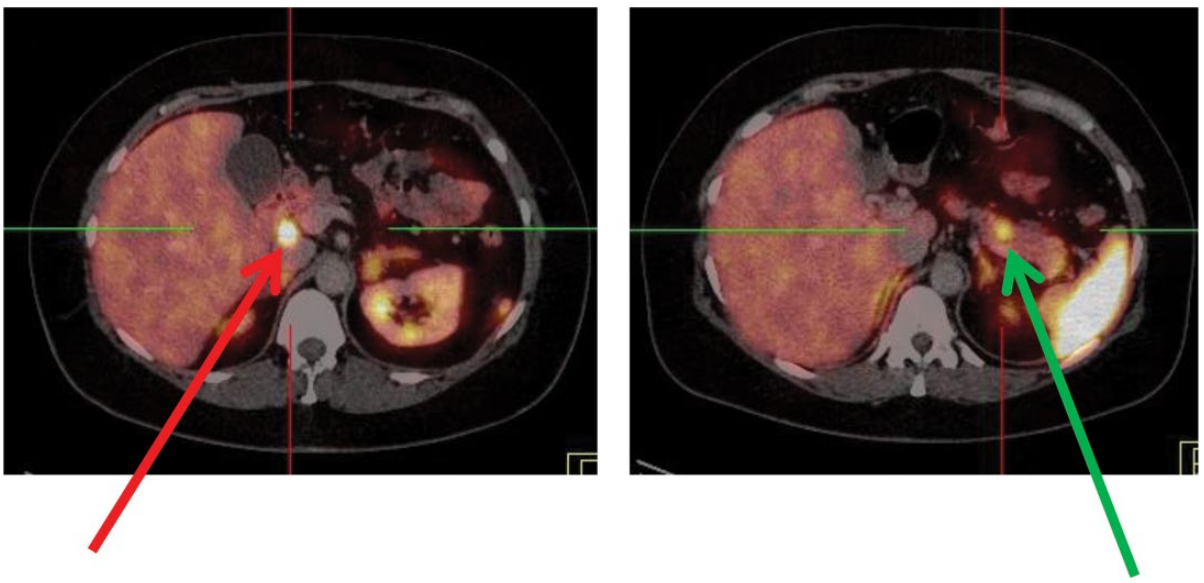

Figure 104.1 [^{68}Ga]DOTA-TOC PET/CT in a 41-year-old patient with known MEN 1 syndrome. She had undergone parathyroidectomy because of hyperparathyroidism 10 years earlier. At present she is diagnosed with hypergastrinemia without clinical manifestation of ZES. Red arrow, duodenal lesion. Green arrow, additional pancreatic lesion; no evidence of metastases.

shown to localize insulinomas with high sensitivity [22,23] and may therefore help to differentiate insulinomas from nonfunctioning PanNETs in the preoperative setting.

Clinical Presentation

Nonfunctioning PanNETs are usually asymptomatic. In cases of advanced disease, they can cause unspecific tumor-associated symptoms such as abdominal or back pain, jaundice, or weight loss.

Gastrinomas cause the *Zollinger–Ellison syndrome* with clinical manifestations resulting from gastric acid hypersecretion such as severe peptic disease (peptic ulcerations), gastroesophageal reflux disease, and diarrhea. Peptic ulcer bleeding may be the presenting symptom in some patients. The use of proton pump inhibitors (PPIs), however, may mask the symptoms of ZES and delay diagnosis. Concomitant hyperparathyroidism may enhance hypergastrinemia-associated symptoms. With biochemical screening in patients with a known diagnosis of MEN 1, hypergastrinemia can be detected early before clinically relevant ZES develops. Patients with MEN 1 with ZES present at an earlier age (mean 32–35 years) than patients with sporadic gastrinomas.

Insulinomas present with symptoms of hypoglycemia (headache, diplopia, confusion, dizziness, abnormal behavior, amnesia, rarely seizures and coma) and symptoms resulting from the counterregulation of the autonomic nervous system (sweating, weakness, hunger, tremor, anxiety, palpitations). Patients often gain weight. The presence of a Whipple triad remains useful in suspecting underlying insulinoma [24]. The triad consists of symptoms of hypoglycemia, plasma glucose level <40 mg/dL, and relief of symptoms with administration of glucose. Insulinomas in patients with MEN 1 often occur at young age (many <20 years), whereas sporadic cases generally occur in patients aged >40 years [3].

A *glucagonoma syndrome* is found in <3% of patients with MEN 1 and is characterized by the presence of a necrolytic migratory erythema (a characteristic skin rash), weight loss, anemia, and glucose intolerance or diabetes. In clinical practice, the glucagnoma syndrome is rare and more often pancreatic lesions stain positive for glucagon with slightly increased glucagon serum levels, although without the clinical syndrome [3,8].

The *Verner–Morrison syndrome*, also called pancreatic cholera or WDHA syndrome (watery diarrhea, hypokalemia, and achlorhydria) is caused by hypersecretion of VIP. Patients suffer from excessive diarrhea with electrolyte and pH disturbances and dehydration. Less than 1% of patients with MEN 1 present with Verner–Morrison syndrome [3,8].

In a patient with MEN 1, more than one hypersecretion syndrome can develop over the years.

Surgical Treatment

A proven organic hyperinsulinism is an indication for surgical treatment due to the lack of adequate medical therapy. The surgical strategy has to be individualized, taking the localization and size of tumor(s) (about 30% multiple insulinomas) into consideration. The identification of the insulinoma(s) within multiple PanNETs can be challenging and new options with endoscopic fine needle biopsy and GLP1R-based PET/CT may be helpful but availability and data are limited. If only one tumor is visualized or one dominant tumor (<10 mm) with smaller (≤5 mm) additional PanNETs, enucleation or pancreatic segmental resection is recommended [8]. For larger insulinomas near the main pancreatic duct, spleen-preserving left pancreatectomy is indicated. Routine lymphadenectomy is not indicated. A partial pancreaticoduodenotomy (PPD) is rarely necessary only in case of a large insulinoma of the pancreatic head. Intraoperative ultrasound and determination of the insulin/glucose ratio have been suggested for assessing the success of removal of the insulinoma [25].

In patients with glucagonomas and VIPomas, the primary tumor is often located in the pancreatic tail and surgical removal with curative intention (left pancreatectomy with lymph node resection) is the treatment of choice. In metastasized cases with functioning pancreatic tumors, interdisciplinary discussion of operative debulking, medical treatment, peptide receptor radionuclide treatment (PRRT) and hepatic artery embolization or combinations thereof is necessary.

The indication for surgery and the operative technique in patients with MEN 1-associated ZES are controversial. About 90% of patients with MEN 1 have multiple tumors in the duodenum and a favorable long-term prognosis if only small tumors (<2 cm) or no tumors are present on preoperative imaging examination [26]. Although the gastrinomas in MEN 1 patients are usually duodenal, a PanNET of ≥2 cm has been suggested as a surrogate parameter to indicate surgery which always has to include duodenectomy and systematic lymphadenectomy [8]. The so-called Thompson procedure additionally comprises subtotal left pancreatectomy with preservation of the spleen and enucleation of tumors of the pancreatic head [27]. Most patients can be rendered eugastrinemic with this approach but cure is rare. Therefore, some centers suggest a more aggressive surgical approach with PPD to provide a higher rate of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cure [28,29]. The increased likelihood of cure has to be weighed against an increased operative mortality and long-term morbidity in each individual case and the patient's preference must be considered.

Surgery may also have a role in metastatic disease if at least 90% or all of the identifiable tumor burden can safely be removed [8]. Cure by surgery in metastatic disease is rare (<10%); all patients should be discussed in an experienced multidisciplinary tumor board.

Nonfunctioning (NF) PanNETs also harbor the risk of malignant transformation and there is ongoing debate regarding the correct timing and extent for surgical intervention. Most centers and also the recent guideline recommend surgery for NF PanNETs of 2 cm size or larger or for smaller tumors demonstrating significant growth under surveillance [8,11]. A documented grade 2 PanNET is associated with higher malignant potential and therefore also judged as indication for surgery regardless of size [30,31].

There is no clear consensus on the extent of surgical resection. Most authors suggest left pancreatectomy with enucleation of tumors of the pancreatic head with lymphadenectomy, but sole enucleation and also more aggressive approaches have also been proposed. A recent metaanalysis demonstrated no differences in survival and reoperation rate in patients with sole enucleations compared to major pancreatic resections, but a higher recurrence rate and a lower rate of endocrine insufficiency [32].

Medical Treatment

The principles of medical treatment of PanNETs in MEN 1 are similar to those in sporadic cases as studies specifically for MEN 1 are very limited.

Medical Treatment in Functioning Tumors

In patients with gastrinoma, treatment with PPI is indicated to suppress hyperacidity. The recommended starting dose is equivalent to omeprazole 40–60 mg b.i.d. in MEN 1/ZES [26]. Long-acting somatostatin analogues such as octreotide-LAR or lanreotide autogel also control acid secretion and can be added to PPI, which is the basic treatment of choice because of its effectiveness and the ease of oral intake.

In patients with insulinoma, prior to mostly curative surgery, intravenous glucose administration in addition to frequent small carbohydrate meals may be necessary. Additional medical treatment is mainly indicated in the rare metastatic cases and includes diazoxide (in combination with diuretics), somatostatin analogues (SSA) (which should be started in the hospital to exclude worsening of hypoglycemia, which also has been reported), and the mammalian target of rapamycin (mTOR) inhibitor everolimus [33].

In patients with VIPomas and glucagonomas, SSA can control the hypersecretion syndrome. Electrolyte shifts and malnutrition should be treated before surgery. Particularly in patients with ZES, hyperparathyroidism should be corrected first (usually by surgery or if not possible, by calcium-sensing receptor agonists such as cinacalcet) as hypercalcemia worsens hypergastrinemia [8].

Medical Treatment for Tumor Control

Medical treatment with antiproliferative intention is usually started in patients with nonresectable or metastatic disease. Nevertheless, one retrospective study as well as a recent prospective study suggested that treatment with SSA in patients with MEN 1 syndrome and small (<2 cm) PanNETs may delay tumor progression and the need for surgery [34,35].

Somatostatin analogues can be administered for antiproliferative purposes in patients with metastatic PanNETs showing slow tumor growth. The CLARINET trial has proven the efficacy with respect to progression-free survival (PFS) in somatostatin receptor-positive (sporadic) gastroenteropancreatic neuroendocrine tumors with a proliferation rate Ki-67 not exceeding 10% [36].

In patients with a high tumor load or rapid tumor growth, chemotherapy with streptozotocin and 5-fluorouracil or temozolomide and capecitabine is indicated [37,38]; in patients with liver-predominant disease, chemoembolization is an alternative. Two molecular-targeted treatments are approved for metastatic PanNET: the multikinase inhibitor sunitinib and the mTOR inhibitor everolimus. In placebo-controlled trials, both drugs demonstrated a doubling of PFS compared with placebo [39,40]. Although the studies included mainly non-MEN patients (two patients with MEN 1 in the sunitinib trial; in the everolimus trial MEN status was not provided), it seems plausible that the results also apply for PanNETs in MEN 1 syndrome which is supported by a recent retrospective study [41].

Peptide receptor radionuclide treatment is also used for symptomatic as well as tumor control in receptor-positive PanNETs although currently prospective controlled data for the PanNET are lacking [42,43]. The efficacy for metastatic tumors with a hereditary background of MEN has been recently demonstrated in a case series [44].

Follow-up

Patients with MEN 1 syndrome or *MEN1* gene carriers should be offered a program of combined clinical, biochemical, and radiologic screening and follow-up; an

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Table 104.1 Suggested program of combined clinical, biochemical, and radiologic screening and follow-up.

Examination	Interval	Extent
Clinical evaluation	Annually	Extensive history of symptoms of tumor manifestations and physical examination
Biochemical screening	Annually	Ca, parathyroid hormone, gastrin, fasting glucose, insulin, CgA, glucagon, VIP, prolactin, IGF-1
Functional testing	No routine investigation, suspicion of gastrinoma	Gastric pH, secretin test, or Ca infusion test
	Suspicion of insulinoma	Fasting test
Abdominal imaging	Annually	EUS, MRI, or CT or [^{8}Ga] DOTA-TOC PET/CT
Imaging of the chest	Every 1–2 years	CT or MRI or [^{68}Ga] DOTA-TOC PET/CT
Imaging of the pituitary gland	Every 3 years	MRI

CgA, chromogranin A; IGF-1, insulin-like growth factor 1; for other abbreviations, see text.

example of a follow-up scheme is summarized in Table 104.1 [3]. The program should be individualized according to initial tumor size, Ki-67 value (if available), documented tumor growth rate, the patient's (family) history, and also patient preference. If rapid growth is excluded in initial follow-up, extension of the screening interval may be appropriate [8,45].

There is no consensus regarding the value of tumor markers like chromogranin A (CgA) or pancreatic polypeptide (PP) in follow-up nor for the best imaging technique (MRI, endoscopic ultrasound, [^{68}Ga]DOTA-TOC PET/CT, combinations therof) [8].

Prognosis

Despite the fact that life expectancy in patients with MEN 1 has increased in recent decades, 50–70% of patients with MEN 1 will die of causes directly related to MEN 1 [46]. Whereas in early series patients often died as a result of complications of hormonal effects of the tumors such as upper gastrointestinal bleeding resulting from ZES or renal complications as a consequence of hyperparathyroidism, today there is a shift toward death from malignancy [4]. PanNETs and especially the more aggressive thymic carcinoid tumors are associated with an increased risk of death [46] and the risk of dying from a malignant nonendocrine tumor is also elevated [4,5]. The presence of liver metastases is the most important prognostic factor. In the Dutch MEN 1 database, 10-year overall survival in patients with and without hepatic metastases was 50% and 86%, respectively [47]. Large PanNETs, grade 2 tumors, thymic NETs, presence of ZES, and male sex have also been reported as poor prognostic factors [4,30,47,48].

Nonfunctioning Pancreatic Neuroendocrine Neoplasms: Diagnosis and Management Principles

Takao Ohtsuka, Yuto Hozaka, and Hiroshi Kurahara

Department of Digestive, Breast and Thyroid Surgery, Graduate School of Medical Sciences, Kagoshima University, Kagoshima, Japan

Definition

Among pancreatic neuroendocrine neoplasms (PanNENs), nonfunctioning PanNEN (NF-PanNEN) is defined as tumor with no specific symptoms due to excess of hormonal secretion. Therefore, PanNENs with a high level of serum hormone or positive result for specific hormone on immunohistochemical assessment, while no specific symptoms are observed, are managed as NF-PanNENs.

Pathology

According to the World Health Organization (WHO) classifications of 2017 and 2019 [1,2], NENs, including PanNENs, are divided into well-differentiated neuroendocrine tumor (NET) and poorly differentiated neuroendocrine carcinoma (NEC). NETs are graded using mitotic count and/or Ki-67 labeling index as G1 (mitotic count <2 per 10 high power fields [HPF] and/or <3% Ki-67 index), G2 (mitotic count 2–20 per 10 HPF and/or 3–20% Ki-67 index), and G3 (mitotic count >20 HPF and/or >20% Ki-67 index). Poorly differentiated NECs are further divided into small cell type and large cell type, and NECs usually show mitotic count >20 HPF and/or >20% Ki-67 index. A combination of NEN and other pathologic subtypes such as adenocarcinoma and acinar cell carcinoma is classified as mixed neuroendocrine-nonneuroendocrine neoplasm (MiNEN).

Positive staining for specific neuroendocrine markers such as chromogranin A and/or synaptophysin is necessary to make a definitive diagnosis of NEN. Of note, some NF-PanNENs show positive staining for several specific hormones including insulin, glucagon, pancreatic polypeptide, or serotonin on immunohistochemical assessment, although staining pattern is focal and thus there is no specific symptom [3].

Mechanism of Tumorigenicity

Neoplastic cells of PanNETs are considered to originate from neuroendocrine stem cells in the islets of Langerhans or pancreatic ductal epithelium. Several genetic alterations which may be associated with the tumorigenicity of PanNETs have been reported. Jiao et al. [4] showed that alterations of *DAXX/ATR*, *MEN1*, and mTOR pathway genes are frequently observed in well-differentiated PanNETs. It is well known that NF-PanNETs are often accompanied by hereditary diseases including multiple endocrine neoplasm type 1 (MEN 1), von Hippel–Lindau disease, von Recklinghausen disease, and tuberous sclerosis (TS). On the other hand, poorly differentiated PanNECs are reported to have alterations in *p53*, *Rb*, and *bcl-2*, and therefore are considered to be included in a different disease group from well-differentiated PanNETs [5].

Clinical Findings

PanNENs account for about 2% of all pancreatic neoplasms, and NF-PanNETs are the most frequent PanNENs (40–60%), followed by insulinoma (~20%) and gastrinoma (~10%). In the Japanese nationwide survey [6], the estimated prevalence of PanNENs in 2010 was 2.69/100 000 with annual onset incidence of 1.27/100 000 including 65.5% of NF-PanNENs. Most NF-PanNETs are solitary, but occasionally multiple, especially in hereditary diseases. Well-differentiated NF-PanNETs grow slowly but large NF-PanNETs have the potential to metastasize to lymph nodes and/or liver. Of note, NF-PanNETs sometimes acquire hormonal production and its relevant symptoms with progression [1,2]. On the other hand, poorly differentiated NECs show quite high malignant behavior, and most

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.
© 2023 John Wiley & Sons Ltd. Published 2023 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/beger/thepancreas4e

PanNECs are found to be unresectable because of distant metastases at the time of diagnosis. The frequency of PanNEC among NF-PanNENs was 2–10%, and associated MEN 1 was observed in 4–30% of NF-PanNETs. Those distributions are different among races [6].

Symptoms

Most patients with NF-PanNENs do not have specific symptoms, and the number of patients diagnosed as having asymptomatic small NF-PanNET at the time of medical examination or during surveillance for other diseases has recently been increasing. Patients with large NF-PanNENs often present with symptoms such as abdominal pain, discomfort, distention, weight loss, nausea, or palpable mass. Involvement of the bile duct or pancreatic duct leads to jaundice, obstructive pancreatitis, or diabetes mellitus.

Diagnosis

Typical radiologic findings in well-differentiated NF-PanNETs (G1) are well-demarcated homogeneous hypoechoic lesion on ultrasonography, well-demarcated enhanced solid tumor on early phase enhanced computed tomography (CT) (Fig. 105.1a), low-intensity tumor on T1-weighted images and high-intensity lesion on T2-weighted images on magnetic resonance imaging (MRI). Large NF-PanNETs often have cystic change or calcification, which are reflected in the radiologic findings (Figure 105.1b,c). Lesions which should be discriminated from well-differentiated PanNETs because of the similarity of radiologic findings include acinar cell carcinoma, solid and pseudopapillary neoplasm, solid-type serous cystic neoplasm, metastatic pancreatic tumor from renal cell carcinoma, and accessory spleen.

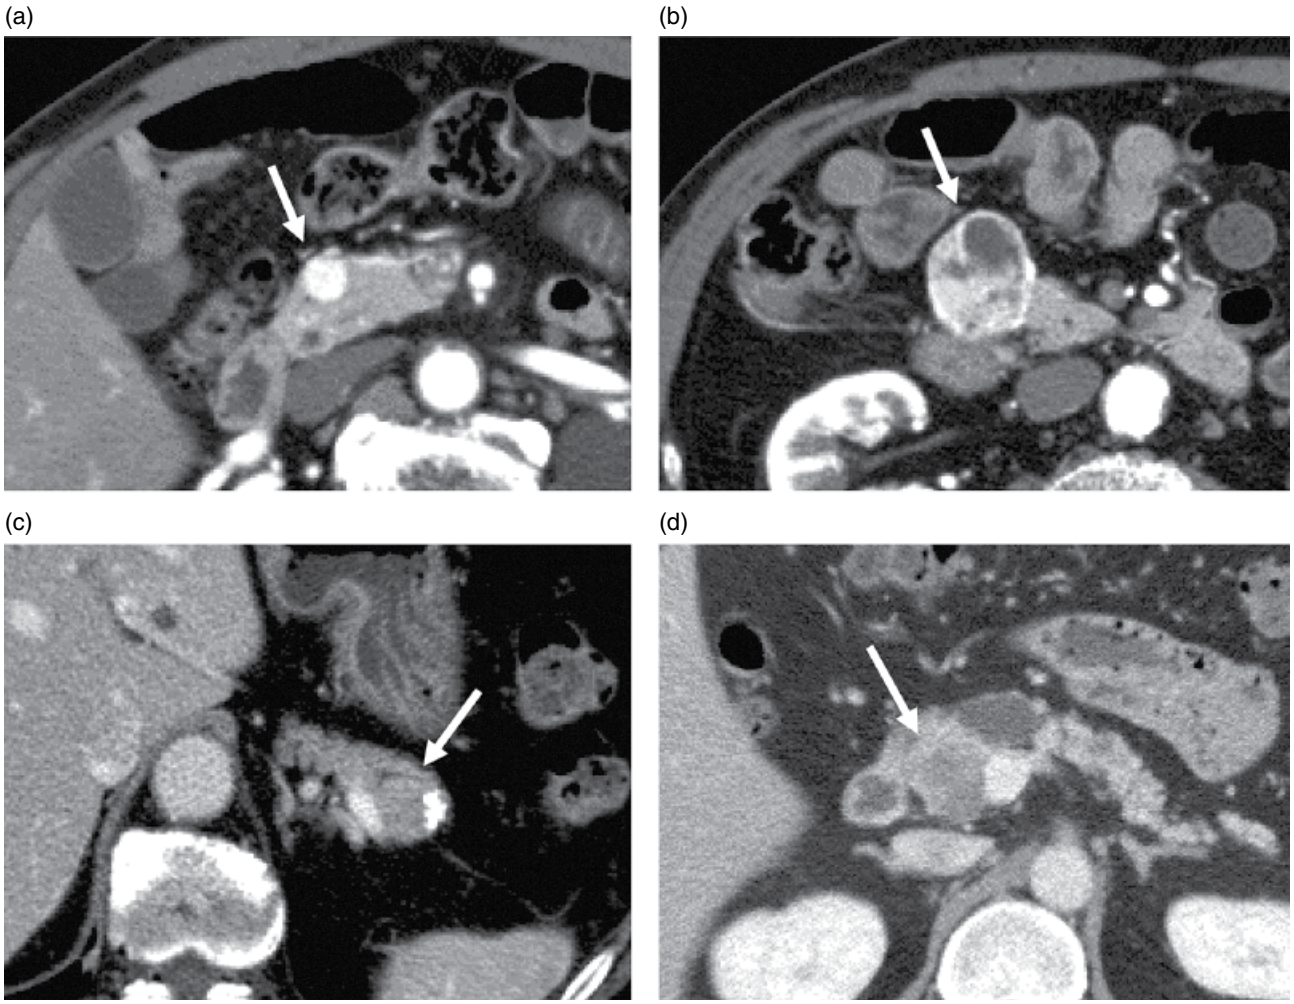

Figure 105.1 Computed tomography findings of nonfunctioning pancreatic neuroendocrine tumor. (a) Well-demarcated enhanced lesion in the pancreas head (arrow, 13 mm, G1). (b) Enhanced lesion with cystic change in the pancreas head (arrow, 35 mm, G2). (c) Lesion with calcification in the pancreas head (arrow, 23 mm, G1). (d) Low-density lesion in the pancreas head with atrophy of distal pancreas (arrow, 34 mm, NEC).

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Somatostatin receptor scintigraphy is applied for detection of metastatic lesions, and enhanced MRI is also useful to detect small hepatic metastases. Serum chromogranin A concentration is used to assess disease control during chemoradiotherapy or to detect recurrence after curative resection.

However, a PanNEC has various radiologic findings and sometimes shows an irregular low-density solid lesion on enhanced CT (Figure 105.1d), which is similar to the finding for pancreatic ductal adenocarcinoma.

For a definitive diagnosis, cytologic assessment under endoscopic ultrasound-guided fine needle aspiration (EUS-FNA) is mandatory, and histologic grading can also be evaluated if enough neoplastic cells (usually over 2000 cells) can be obtained [7].

Table 105.1 presents a brief summary of the diagnostic issues.

Table 105.1 Summary of diagnosis and treatment principles for nonfunctioning pancreatic neuroendocrine neoplasm.

1) Well-differentiated PanNET (G1–G3)
   a) Diagnosis
      Typical radiologic findings of primary lesion
         Ultrasonography; well demarcated homogeneous, hypoechoic
         Enhanced computed tomography; well-demarcated enhanced lesion in early phase
         Magnetic resonance imaging; T1-low intensity, T2-high intensity
         Other findings; cystic change, calcification, etc.
      Differential diagnosis
         Acinar cell carcinoma, solid-pseudopapillary neoplasm, solid type serous cystic neoplasm, accessary spleen, etc.
      Definitive diagnosis
         Endoscopic ultrasonography-guided fine needle aspiration
      Detection of metastatic lesion
         Systemic; computed tomography, somatostatin receptor scintigraphy
         Liver; enhanced magnetic resonance imaging
   b) Treatment
      Primary
         <2 cm
         ≥2 cm
         Tumor with asymptomatic, occasionally found by imaging, <20 mm in size, G1 and low G2, can be observed without resection based on the consideration of patient's general condition as well as expected invasiveness of the operation
         In multiple tumors of MEN 1, remove only functioning tumor and high-risk nonfunctioning tumor (>1–2 cm in diameter) to avoid total pancreatectomy
      Metastases
         Resection, if possible, or multidisciplinary treatment including debulking surgery, regional ablation therapy, systemic chemotherapy, molecular-targeted therapy, somatostatin receptor agonist, etc.
2) Poorly differentiated PanNEC
   a) Diagnosis
      Radiologic findings of primary lesion
         Ultrasonography; irregular hypoechoic
         Computed tomography; irregular low density
         Magnetic resonance imaging; T1-low intensity, T2-high intensity
      Differential diagnosis
         Pancreatic ductal adenocarcinoma, etc.
      Definitive diagnosis
         Endoscopic ultrasonography-guided fine needle aspiration
      Detection of metastatic lesion
         Computed tomography, magnetic resonance imaging, positron emission tomography
   b) Treatment
      Resectable primary
         Resection + adjuvant chemotherapy using platinum-based regimen
      Unresectable primary or metastases
         Chemotherapy using platinum-based regimen

Treatment

Surgical Treatment for Localized Lesion

Curative resection should be considered as the first aid of treatments in all cases of localized well-differentiated NF-PanNETs [8–10]. However, National Comprehensive Cancer Network (NCCN) guidelines [8] recommend that asymptomatic well-differentiated NF-PNETs (less than 20 mm in diameter), which are occasionally found by imaging, can be observed without resection based on consideration of the patient's general condition as well as the expected invasiveness of the operation. The European Neuroendocrine Tumor Society (ENETS) guidelines [9] also include the option that NF-PanNETs with tumor size of 2 cm or less, with characteristics such as G1, low G2, asymptomatic, mainly in the head, no radiologic signs suspicious for malignancy, patient factors (personal wishes, age, comorbidities, etc.), can be observed without resection and surveyed every 6–12 months.

Surgery for localized well-differentiated NF-PanNETs ranges from enucleation, organ-preserving pancreatectomy to standard pancreatectomy with regional lymph node dissection, and surgical treatment strategy is determined based on tumor size, the invasiveness and presence of regional lymph node metastases on imaging studies. The rate of lymph node metastases in small, well-differentiated NF-PNET remains unclear and thus, sampling of the regional lymph node is always necessary even in enucleation or organ-preserving pancreatectomy for small NF-PanNETs. In several guidelines [8–10], small NF-PanNETs are considered as being those with a tumor size of less than 2 cm with no sign of invasiveness or lymph node metastasis. There is no evidence showing the benefit of neoadjuvant therapy before operation or adjuvant therapy after curative resection for well-differentiated NF-PanNETs and therefore, those adjuvant therapies are not recommended at this time.

Surgical treatment for resectable PanNEC is standard pancreatectomy with regional lymph node dissection, and adjuvant therapy using platinum-based chemotherapy in proportion to the regimen for small cell carcinoma of the lung is recommended [8].

PanNETs are clinically observed in 50–60% of MEN 1 patients, while all the autopsy cases of MEN 1 have PanNETs, although they are microlesions [11]. Most cases are multiple, and the most frequent type is NF-PanNET. Presence of PanNET is an important prognostic factor in MEN 1 [12].

Surgical treatment for multiple NF-PanNETs in MEN 1 is complicated. Several guidelines [8–10] recommend removing only functioning PanNETs and high-risk NF-PanNETs (over 1 or 2 cm in diameter) to avoid total pancreatectomy; for example, distal pancreatectomy with enucleation of the PanNETs in proximal pancreas, or pancreatoduodenectomy with enucleation of the PanNETs in distal pancreas.

Prognosis for NF-PanNENs after resection depends on histologic grade, and five-year survival rates are 80–100% in PanNET G1, 50–70% in PanNET G2, and 0–30% in PanNET G3/PanNEC [13]. Some patients experience recurrence over 10 years after operation, and therefore long-term postoperative surveillance is necessary.

Multidisciplinary Treatment for Metastatic Lesions

The most frequent site for distant metastases of PanNETs is the liver, and 70% of hepatic metastases are diagnosed as multiple lesions at the time of initial assessment [14,15]. In recurrent cases after resection, some patients experience hepatic metastasis over 10 years after curative operation, as described above. Resectable hepatic metastases without extrahepatic metastases are usually treated by operation with or without regional ablation therapies such as radiofrequency ablation and transarterial chemoembolization. Even in unresectable cases, aggressive multidisciplinary treatment including debulking surgery might lead to over 50% five-year survival rate, if over 70–90% of the lesions can be removed [14,15]. Asymptomatic and slow-growing unresectable small volume of metastatic NF-PanNETs can be observed without any treatment until signs of growth or symptoms are apparent. Liver transplantation for unresectable hepatic metastases from PanNET is not recommended because of unsatisfactory outcomes [16].

The necessity of resection of the primary lesion in cases of synchronous unresectable hepatic metastases remains controversial. One report [17] claimed that resection of the primary lesion would lead to definitive diagnosis of PanNET with accurate histologic grade as well as subsequent application of such specific therapies for hepatic metastases as transarterial chemoembolization and radiofrequency ablation. On the other hand, another report [18] showed that there was no difference in survival between patients with synchronous unresectable hepatic metastases who underwent resection of primary PanNET and those without primary resection. Due to recent advances in the technique of EUS-FNA for the definitive diagnosis of PanNET with histologic grade, and development of new drugs including molecular-targeted drugs, various types of somatostatin receptor analogue, and radionucleotide-labeled peptide targeting somatostatin receptor, resection of primary tumor is not always necessary in cases with synchronous unresectable hepatic metastases of PanNETs.

Surgical indication for extrahepatic metastases is limited, because most of these cases also have hepatic metastases, and indication depends on the status of hepatic metastases.

Treatment principles for NF-PanNENs are summarized in Table 105.1. Medical treatments for PanNETs include chemotherapy (streptozocin, dacarbazine), molecular-targeted therapy (everolimus, sunitinib), and somatostatin receptor analogue therapy including radionucleotide therapy, and details of these therapies are described elsewhere.

Medical and Nucleotide Treatment of Neuroendocrine Tumors of the Pancreas

Marina Tsoli and Gregory Kaltsas

1st Department of Propaedeutic and Internal Medicine, Laiko Hospital, National and Kapodistrian University of Athens, Athens, Greece

Introduction

Pancreatic neuroendocrine neoplasms (pNENs), although relatively rare, are increasingly being diagnosed following the introduction of more sensitive imaging techniques. Although a number of pNENs are capable of synthesizing and secreting biochemically active substances leading to distinct clinical syndromes (functioning tumors), the great majority are nonfunctioning [1] (Table 106.1). According to the proliferative index (PI) Ki-67, defined by immunohistochemical staining for nuclear Ki-67 protein expression, pNENs are classified into grade 1 (G1) or 2 (G2), if Ki-67 PI is ≤2% or between 3% and 20% respectively, and grade 3 (G3) if Ki-67 PI is >20%. G3 neoplasms are further subdivided into well-differentiated G3 neuroendocrine tumors (G3 NETs) or poorly differentiated G3 neuroendocrine carcinomas (G3 NECs) [2].

Surgery is the mainstay of treatment of pNENs but in recent decades there has been a considerable evolution of medical treatments that are used for locally advanced or metastatic disease not amenable to surgical resection. The goals of systemic treatment are to induce tumor shrinkage and/or prevent further tumor growth, relieve symptoms related to secretory syndromes, and increase overall survival. Treatment decisions are based on several parameters, including the extent of disease, tumor differentiation, and the presence of clinical symptoms (Table 106.2). In the past, chemotherapy has been the main therapeutic approach substantiated by a few well-controlled but mostly retrospective studies but the options for systemic therapy have continuously increased [3–5]. Long-acting somatostatin analogues (SSAs) have been used for the control of symptoms secondary to secretory syndromes as well as for tumor growth control, exhibiting mainly a stabilizing effect (1).

Recent phase III studies have introduced new therapeutic approaches and several retrospective studies have provided good-quality data on the efficacy of new and previously utilized treatments. Several international societies have established guidelines to aid pNENs management and several therapeutic algorithms have been proposed (Figure 106.1), but there are still some unresolved issues regarding the most appropriate first-line therapy and/or sequence of treatments for individual patients upon disease progression [6–8].

Somatostatin Analogues (SSAs)

Somatostatin is a neuropeptide secreted in the gastrointestinal tract and brain. It acts via interaction with five somatostatin receptor subtypes (SSTR1–5) and inhibits the secretion of various hormones and may also exert immunomodulatory, cytotoxic, and apoptotic actions [9]. SSTR2 is found predominantly in NENs of gastroenteropancreatic (GEP) origin.

Somatostatin analogues act by binding with high affinity to SSTRs and exert antisecretory and antiproliferative activity [9]. Long-acting SSA formulations such as octreotide LAR and lanreotide Autogel® are currently available and are administered once monthly.

The first evidence for the antiproliferative activity of SSAs came from the PROMID clinical trial, a randomized placebo-controlled phase III study that

showed a significantly prolonged time to progression (TTP) in patients with well-differentiated locally advanced or metastatic intestinal NENs on treatment with octreotide LAR (hazard ratio [HR] 0.34; 95% confidence interval [CI] 0.20–0.59; I = 0.000072) [10]. Subsequently, the randomized placebo-controlled phase III CLARINET study demonstrated significantly increased progression-free survival (PFS) in patients with locally advanced or metastatic well-differentiated (Ki-67 <10%) GEP-NENs treated with lanreotide compared to placebo [11]. The study showed a benefit in terms of PFS with a HR of 0.58 (95% CI 0.32–1.04) and median PFS of 29.7 months for the group of pNENs [12]. The benefit in PFS was observed regardless of tumor burden. Thus, SSAs are recommended as first-line systemic treatment for tumor growth control in cases of stable or slowly progressive disease.

Although there is no established Ki-67 cut-off value, SSAs are generally recommended in patients suffering from NENs with a Ki-67 up to 10% [13]. Patients with well-differentiated pNENs who are progressing under standard doses of SSAs may benefit from above-label doses [14]. Pasireotide, a new-generation SSA with high affinity for all SSTRs except SSTR4, has been shown to be effective in patients with advanced NENs but recent studies showed no advantage of this agent compared to other SSAs [15].

Common adverse events of SSAs include abdominal pain, diarrhea, nausea, gallstone development, and glucose intolerance [9]. Pasireotide is a potent hyperglycemic agent associated with alterations of glucose metabolism in up to 25% of patients treated [15].

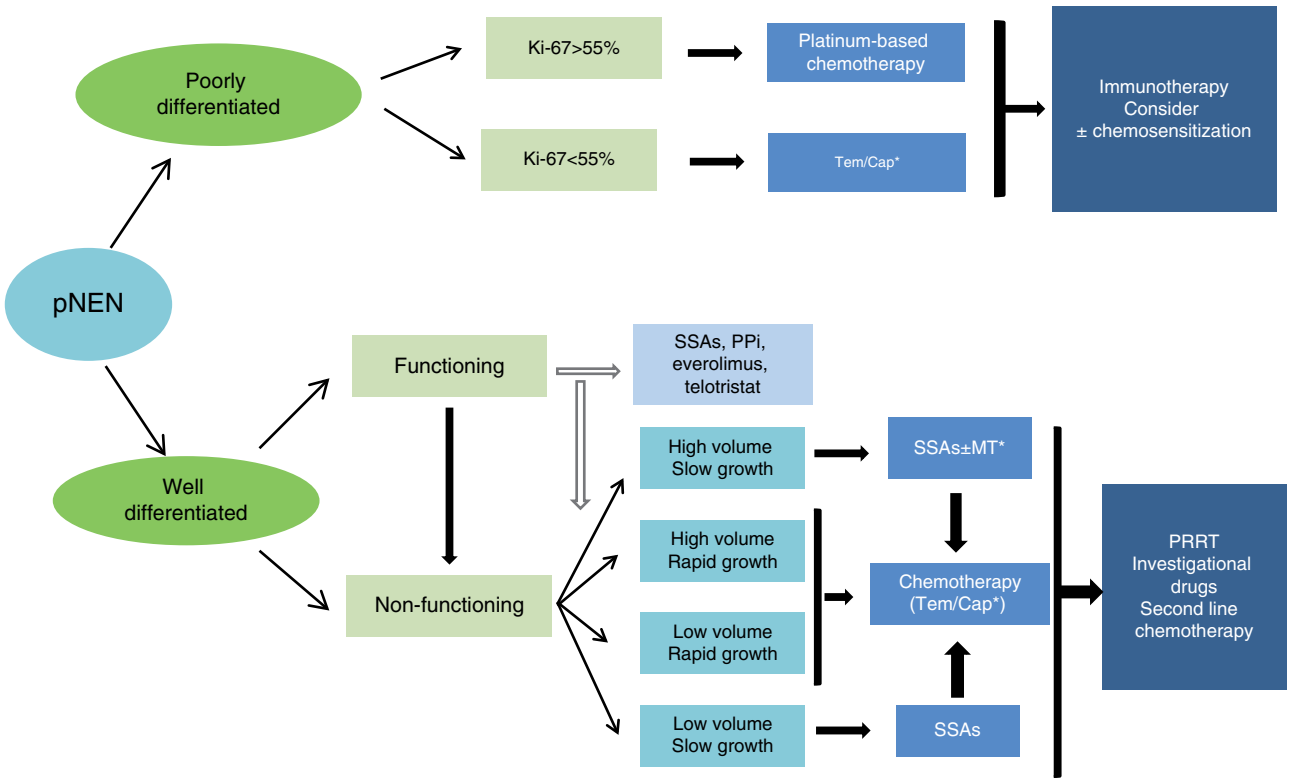

Figure 106.1 Suggested algorithm for the nonsurgical management of pNENs. MT, molecular targeted; PRRT, peptide receptor radionuclide therapy; SSAs, somatostatin analogues; Tem/Cap, temozolomide-capecitabine.

Targeted Agents

Molecular studies have revealed that two main pathways are involved in NEN growth: the vascular endothelial growth factor (VEGF) and the mammalian target of rapamycin (mTOR), and drugs that target these pathways have been proved to be effective in patients with advanced GEP-NENs.

Everolimus is an mTOR inhibitor that has demonstrated antiproliferative action and is recommended as a second- or third-line treatment after failure of SSAs or other agents in well-differentiated NENs. A phase III prospective, randomized, placebo-controlled, double-blind trial (RADIANT 3) showed significant prolongation of PFS with everolimus versus placebo in patients with advanced G1 or G2 pNENs (HR 0.35; 95% CI 0.27–0.45; P <0.001). Objective responses were low (<5%) and independent of prior treatment with chemotherapy [16,17]. Common side-effects of everolimus include glucose intolerance or diabetes, stomatitis, and pneumonitis. Other inhibitors of mTOR complex-1 (mTORC1) and mTOR complex-2 (mTORC2), such as BEZ235, have been studied in patients with pNENs with disappointing results [18].

The tyrosine kinase inhibitor (TKI) sunitinib inhibits the vascular growth factor receptor (VEGFR-2 and -3), platelet-derived growth factor receptor (PDGFR) and stem cell factor receptor (c-kit) and is currently approved for the treatment of metastatic pNENs. The SUN11 trial, a phase III double-blind placebo-controlled study, showed a significant benefit of sunitinib over placebo with improved PFS in patients with pNENs (HR 0.32; 95% CI 0.18–0.55; P = 0.000015) [19,20]. A significantly longer PFS was observed in patients with a Ki-67 <5% while patients with nonfunctioning tumors displayed a higher response rate. However, data on the effect of sunitinib on overall survival are lacking. Common adverse events include nausea, diarrhea, fatigue, neutropenia, hypertension, hypothyroidism, and palmar-plantar erythrodysesthesia [19,20].

In recent years, other antiangiogenic agents have been tested in several trials, albeit involving a limited number of patients with pNENs. Pazopanib inhibits VEGF receptors 1, 2, and 3, and an early study has shown it has some activity in patients with pNENs [21]. Surufatinib, a small molecule inhibitor targeting VEGF receptors, fibroblast growth factor receptor 1 and colony-stimulating factor 1 receptor, showed promising antitumor effects in patients

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with advanced NENs [22]. A recent randomised, double-blind, placebo-controlled, phase III study showed significantly improved PFS with surufatinib compared to placebo (HR 0.49; 95% CI 0.32–0.76; P = 0.0011) in patients with progressive, advanced pNENs [23]. A phase II trial of capozantinib reported a median PFS of 21.8 months while the most promising response rate was reported for lenvatinib (42.3%) [5].

Bevacizumab is a monoclonal antibody against VEGF and has been tested in combination with chemotherapy (5-fluorouracil + streptozotocin) in patients with well-differentiated pNENs displaying a two-year PFS and a two-year overall survival (OS) of 88% [24]. The combination of bevacizumab with temserolimus, an mTOR inhibitor, demonstrated substantial activity with good tolerance in patients with well- and moderately differentiated pNENs [25].

Chemotherapy

In contrast to other gastrointestinal NENs that are typically chemo-resistant, well-differentiated pNENs appear to be sensitive to chemotherapy, including streptozotocin, dacarbazine, and temozolomide as well as fluoropyrimidines. However, most of the studies of chemotherapy in patients with pNENs are retrospective series or small phase II trials [5]. Streptozotocin-based chemotherapy in combination with 5-fluorouracil (5-FU) or doxorubicin has been observed to be effective in the treatment of pNENs and especially in G2 neoplasms or in those with high tumor load [4,13]. The BETTER trial showed that bevacizumab with 5-FU/streptozotocin in patients with progressive metastatic well-differentiated pNENs resulted in a PFS of 23.7 months and a two-year OS of 88% [24]. The combination of oxaliplatin with 5-FU/capecitabine in a few small phase II studies in combination with bevacizumab resulted in response rates of 30–41% [5].

Recent studies have shown that temozolomide (oral derivative of dacarbazine) as monotherapy or in combination with capecitabine (oral derivative of 5-FU) may be an effective treatment option in advanced NENs with tolerable toxicity [26,27] (Figure 106.2). In 2011, a retrospective study showed that the combination of capecitabine and temozolomide (CAPTEM) was associated with a 70% objective response rate, with a median PFS of 18 months and an OS of 92% at two years [27]. A recent phase II trial in patients with advanced pNENs who were randomized to receive CAPTEM vs monotherapy with temozolomide showed improvement in PFS from 14.4 months with temozolomide alone to 22.7 months with the combination, regardless of tumor grade [5].

The Nordic study was the first to report a higher response rate to platinum-based regimens for patients with G3 pNENs and a Ki-67 >55% (42% vs 15%), suggesting that aggressive lesions respond better to these regimens [28]. In contrast, G3 NETs have a significantly worse response to platinum-based chemotherapy than G3 NECs while results with alkylating agents are more encouraging in G3 NET patients [29].

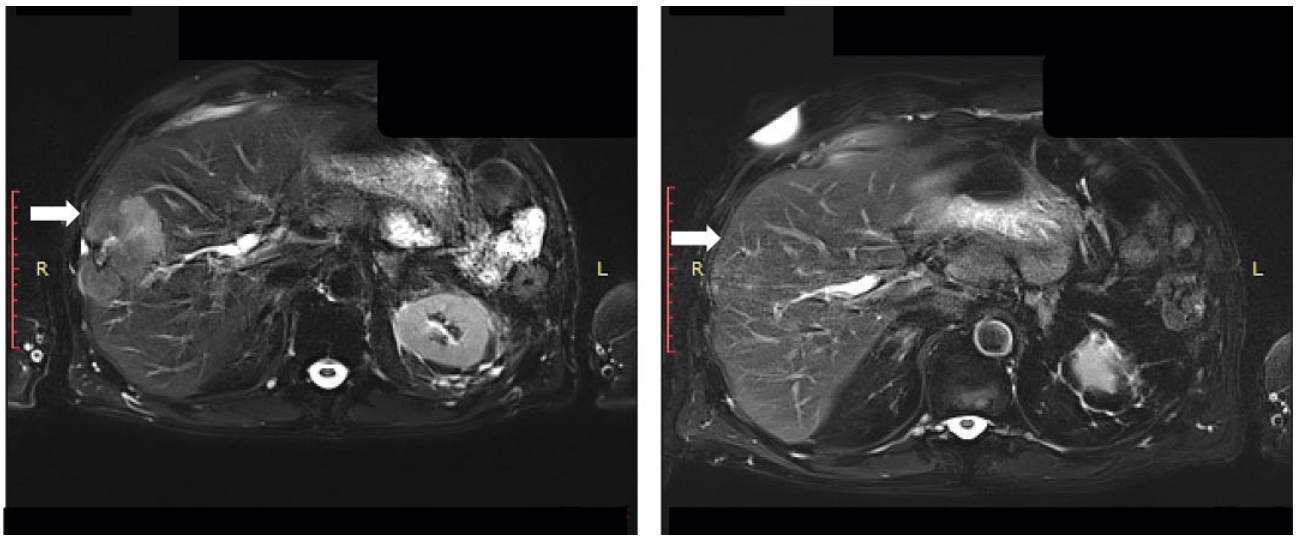

Figure 106.2 Significant liver disease response according to criteria Response Evaluation Criteria in Solid Tumors (RECIST) after one year of treatment with temozolomide-capecitabine.

In clinical practice, systemic chemotherapy is recommended in G1 or G2 tumors with a high tumor load or displaying significant tumor progression in less than 6–12 months and in G3 NENs [6]. In G3 NECs, which frequently have a rapidly progressive clinical course, platinum-based chemotherapy is recommended as a first-line option while FOLFOX (folinic acid, 5-fluorouracil, oxaliplatin) or FOLFIRI (folinic acid, 5-fluorouracil, irinotecan) are indicated as second-line treatment [7]. However, response rates are short-lived and eventually the majority of patients develop progressive disease.

Peptide Receptor Radionuclide Therapy (PRRT)

Peptide receptor radionuclide therapy is a plausible therapeutic option in patients with tumors expressing SSTRs, as it has demonstrated antitumor efficacy and amelioration of refractory hormone secretion syndromes. PRRT consists of a chelator (DOTA) or linker that binds on one side with a SSTR ligand (agonist or antagonist) and a therapeutic particle (yttrium-90 [90Y] or lutetium-177 [177Lu]) on the other [30]. A phase III randomized controlled trial (NETTER-1) showed that ^{177}Lu-DOTATATE was more effective than high-dose octreotide LAR (60 mg) and was associated with significant prolongation of PFS and symptomatic improvement in patients with advanced progressive SSTR-positive intestinal NENs [31]. Unfortunately, there are no randomized phase III studies investigating the efficacy of PRRT in patients with pNENs, but retrospective series and phase II studies have reported a relatively high response rate (24–54%) as well as prolonged PFS and OS.

Brabander et al. investigated the efficacy of PRRT in patients with SSTR-positive NENs, including 197 patients with pNENs. They observed a high response rate (60.9%) and long median PFS (30.5 months) and median OS (70.8 months) that were even more favorable in patients with pNENs that displayed progressive disease at baseline [32].

PRRT is considered an established treatment for G1/G2 NENs while there is promising emerging evidence supporting their effectiveness in patients with G3 disease and positive somatostatin receptor imaging (SRI) [33]. Recent studies have reported high response rates, disease response rates, PFS, and OS. Until further evidence is available, PRRT should be considered for all NET G3 cases and NEC cases with a Ki-67 21–55% with high uptake on SRI. PRRT for NEC with a Ki-67 >55% should only be considered in highly selected patents and used with caution [33].

It has been recently observed that patients with negative fluorodeoxyglucose PET imaging (FDG-PET/CT) displayed better response rates to treatment with PPRT compared with patients with positive FDG-PET/CT [34]. Thus, a scintigraphic assessment estimating both SSTR expression and glucose metabolism may be suggested in order to identify patients with more aggressive FDG-positive NENs, particularly in the context of G3 tumors, as these patients may benefit from combination of PRRT with capecitabine [33,35].

Immunotherapy

Immune checkpoint inhibitors have been shown to be effective in various cancer types such as melanoma and lung carcinoma as antibodies against programmed death receptor 1 (PD-1) and programmed death ligand 1 (PD-L1) enhance T-cell antitumor activity. Recent studies have reported PDL-1 expression in gastroenteropancreatic NENs whereas a significant correlation between PDL-1 expression and tumor grade has been observed [36]. Unfortunately, recent studies on immunotherapy with checkpoint inhibitors in pNENs have produced equivocal results. Pembrolizumab and spartalizumab have been tested in phase I and II trials involving patients with well- and poorly differentiated pNENs, albeit reporting significantly low response rates [37,38].

Management of Secretory Syndromes

A significant number of pNENs secrete biologically active substances that result in the development of functional syndromes. The management of patients with secretory symptoms should aim primarily at reducing the tumor load either with radical resection or with debulking techniques. However, pre- and perioperative medical treatment is usually necessary while it may also be required in a palliative setting [39,40]. When surgery or the application of other cytoreductive techniques fail to control symptoms, medical treatment is introduced aiming at controlling tumor mass and secretory syndrome. Treatment of common and relatively rare secretory syndromes secondary to functioning pNENs is shown in Table 106.1.

Long-acting SSAs (octreotide LAR and lanreotide Autogel) are considered the most effective option for secretory syndrome control in patients with functioning tumors, albeit without substantial effect on tumor load [41]. Above-label doses of SSAs may be required in secretory syndromes refractory to standard doses [42].

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Patients with SSA refractory syndromes may benefit from dose escalation or increased frequency of administration. Supplemental doses of short-acting octreotide may also provide an additive effect in such cases [6,40]. In cases of insulinoma, SSAs should be used with caution as worsening of hypoglycemia may be observed due to inhibition of counterregulatory hormones [43]. Furthermore, treatment with continuous intravenous infusion of octreotide is required in patients with carcinoid syndrome before and during any kind of intervention in order to prevent carcinoid crisis [40]. SSAs can also be used for the treatment of other rare syndromes secondary to the secretion of VIP, glucagon and ectopic hormonal secretion that is occasionally encountered in patients with pNENs.

Recently, the safety and efficacy of PRRT were investigated in 34 patients with metastatic functioning pNENs (G1–G2), including insulinomas, VIPomas, gastrinomas, and glucagonomas [44]. The treatment resulted in partial or complete response in 59% of patients, disease control in 78%, and reduction of symptoms in more than 80%. While the treatment was safe, the authors recommended considering prevention of hormonal crises, including high-dose proton pump inhibitors for those with gastrinoma, fluids, antidiarrheal medications, and short-acting octreotide for VIPomas, and glucose infusion or short-acting octreotide for insulinomas [44].

In patients suffering from insulinoma, the primary treatment target is to avoid hypoglycemic episodes. Frequent small-volume meals enriched in long-acting carbohydrates are suggested while in some cases, especially in metastatic tumors, continuous feeding via a nasogastric or nasoduodenal tube may be required [39]. Diazoxide decreases insulin secretion through inhibition of adenosine triphosphate (ATP)-sensitive potassium channels and has been shown to be effective in approximately 60% of cases. It has been observed to be efficacious in controlling hypoglycemia, in doses 50–300 mg/day (maximum dose up to 600 mg/day), but it is associated with significant adverse events such as hirsutism, edema, and renal impairment [45,46]. In addition, everolimus has been shown to be effective in controlling hypoglycemia in cases of metastatic insulinomas while there are some reports regarding the hyperglycemic action of glucocorticoids [46–48]. Pasireotide, that has been observed to be associated with high glucose levels, could also be an additional option although it has not been specifically evaluated [15].

In patients with Zollinger–Ellison syndrome, treatment with high dose of a proton pump inhibitor (PPI) is recommended to reduce the acid hypersecretion. PPIs can also be administered intravenously in the acute state while add-on treatment with histamine-2 receptor blockers or antacids may also be required [39]. Long-term treatment with PPIs has been shown to be safe, with potential side-effects including PPI-induced achlorhydria that may lead to B12 deficiency and an increased incidence of bone fractures [6].

In some rare cases, pNENs are associated with carcinoid syndrome. In patients inadequately controlled with SSAs, treatment with telotristat etiprate, an oral inhibitor of the enzyme tryptophan hydroxylase, has been shown to result in significant clinical and biochemical control [49]. Recent phase III studies have shown that addition of telotristat in the treatment of patients inadequately controlled with SSAs is associated with significant reduction in the number of bowel movements and 5-hydroxyindoleacetic acid (5-HIAA) levels while a long-term benefit in weight maintenance has also been observed [50,51].

The first step in the treatment of a patient with a VIPoma is to correct the fluid and electrolyte deficits while in some cases intravenous resuscitation with potassium and bicarbonate may be required. In addition to treatment with SSAs and PRRT, case series have reported a symptomatic response rate of 33–100% in patients with VIPoma treated with sunitinib, probably unrelated to its antitumor effect [52,53].

Rare syndromes related to the unique ability of these tumors to synthesize and secrete compounds that traditionally originate from different tissues, leading to the so-called paraneoplastic syndromes, necessitate the administration of additional, more specific treatment [54].

Future Perspectives

The systemic treatment of patients with pNENs is complex and challenging due to the significant heterogeneity of these tumors, while their relatively low incidence makes research efforts difficult. As our understanding of the molecular basis has advanced, several clinical trials have been conducted to investigate the different biologic behavior and response to treatments between well- and poorly differentiated G3 pNENs. Novel agents that target specific genetic and protein regulators of neoplasms have been investigated in multiple studies. A biomarker-based approach is currently under evaluation in an attempt to inform clinicians regarding tumor prognosis and to facilitate the individualized management of patients with pNENs [55]. Genetic and epigenetic alterations, including circulating tumor cells (CTCs), circulating tumor DNA (ctDNA), histone modifications and miRNAs, are being investigated as prognostic factors and predictors of response to treatment.

While monotherapy has already been shown to be effective, there are multiple ongoing trials investigating the efficacy and safety of potential combinations. The efficacy of combination of SSA with targeted agents or SSA with chemotherapy remains to be determined. In addition, the role of PRRT in patients with pNENs as well as in those with G2 or G3 neoplasms should be further investigated. A phase III randomized study (NETTER-2) investigating the efficacy and safety of PRRT in patients with advanced G2 or G3 GEP-NENs is currently ongoing.

Another issue that needs to be addressed is the sequential use of therapeutic options available for NENs. A recent retrospective study, comparing different sequences of treatments in patients with well-differentiated NENs who received first-line treatment with SSA, observed no significant difference in PFS between patients who received high-dose SSA, everolimus, chemotherapy or PRRT [56]. However, prospective studies are required to further clarify this issue.

Conclusion

Treatment of pNENs has evolved over the last decade and has become extremely complex following the introduction of newer therapeutic agents and the accumulation of good-quality information regarding the efficacy and safety of several therapies. Current therapeutic strategies aim to offer an individualized approach that is based on discussion in a multidisciplinary context, not only at diagnosis but also during different lines of treatment. Research regarding different therapeutic choices, in combination or sequentially, in the treatment of patients with advanced pNENs is required. In addition, there is a clear need for the development of specific biomarkers that could help in selecting patients for individualized treatment. Although several relevant societies have proposed therapeutic algorithms based on the findings of recent studies and acquired cumulative experience, there are still some unresolved issues to be addressed from prospective multicenter studies.

Interventional Radiology in the Treatment of Pancreatic Neuroendocrine Tumors

Tetsuya Idichi, Hiroshi Kurahara, and Takao Ohtsuka

Department of Digestive Surgery, Breast and Thyroid Surgery, Kagoshima University, Kagoshima, Japan

Type of Interventional Radiology Treatment

In 2017, the World Health Organization classified pancreatic neuroendocrine neoplasms (PanNENs) into well-differentiated pancreatic neuroendocrine tumors (PNETs) and poorly differentiated neuroendocrine carcinoma (PanNEC) [1]. PanNEC is not indicated for interventional radiological therapy because tumor progression is rapid and often causes multiorgan metastases. On the other hand, interventional radiologic treatments can be performed in PanNETs. The reasons for this preference are that PanNETs show morphologic well-demarcated lesions and are relatively slow growing, even at metastatic sites, and over 90% of the blood supply to metastatic lesions in the liver is reported to be provided by the hepatic artery [2] (Figure 107.1). Therefore, as is the case for hepatocellular carcinomas, transarterial embolization (TAE), transarterial chemoembolization (TACE), and radiofrequency ablation (RFA) are applied for metastatic PanNETs in the liver. Microwave coagulation therapy, laser interstitial thermotherapy, and cryotherapy have recently been incorporated as potential advances in the various effective treatment options for unresectable PanNETs.

Liver metastases from PanNETs are morphologically classified into three patterns according to the European Neuroendocrine Tumor Society (ENETS) guidelines [3]: simple (unilobar or limited), complex (bilobar), and diffuse pattern. Simple and complex patterns without extrahepatic metastases are usually treated by curative resection, while diffuse pattern is treated by multidisciplinary treatment including systemic medication and surgical debulking with regional ablation therapies such as TAE/TACE and RFA. Owing to recent advances in surgical techniques and the development of systemic medication using anticancer agents, molecular targeted drugs, and peptide receptor analogues, the roles of TAE/TACE and RFA have been limited to providing relief of the hormonal symptoms caused by rapid growth of the tumor or the adjuvant therapy during or after operation [3–9].

TAE/TACE

TAE/TACE are used in the multidisciplinary treatment for unresectable liver metastases from PanNETs (Table 107.1). Therefore, the effects of TAE/TACE alone on survival remain unclear; however, TAE/TACE are reported to provide a decrease of 50–90% of the symptoms caused by hormonal hypersecretion, with a prolonged effect of 6–53 months and a time to progression of 10–19 months [2]. The reported five-year survival rate of TAE/TACE ranges widely from 0% to 80%, because the conditions, such as the range of tumor spread, timing of the TAE/TACE during multidisciplinary treatment, and other treatments subsequently performed after TAE/TACE, are different among the reports [2].

In TAE, histoacryl, in conjugation with lipiodol, gel forms particles with or without lipiodol, polyvinyl alcohol foam, and microspheres using glass or resin, which are used as embolic agents [2]. Several chemotherapeutic drugs, such as doxorubicin, streptozocin, dacarbazine, adriamycin, cisplatin, and mitomycin C, are used in conjugation with lipiodol during TACE [2,7,8]. Drug-eluting beads (DEB) preloaded with doxorubicin have been used as a drug delivery device with a pharmacokinetic benefit in a novel TACE technique, usually defined as DEB-TACE [8].

A recent trend in transarterial technique is radioembolization using a radioconjugated somatostatin analogue.

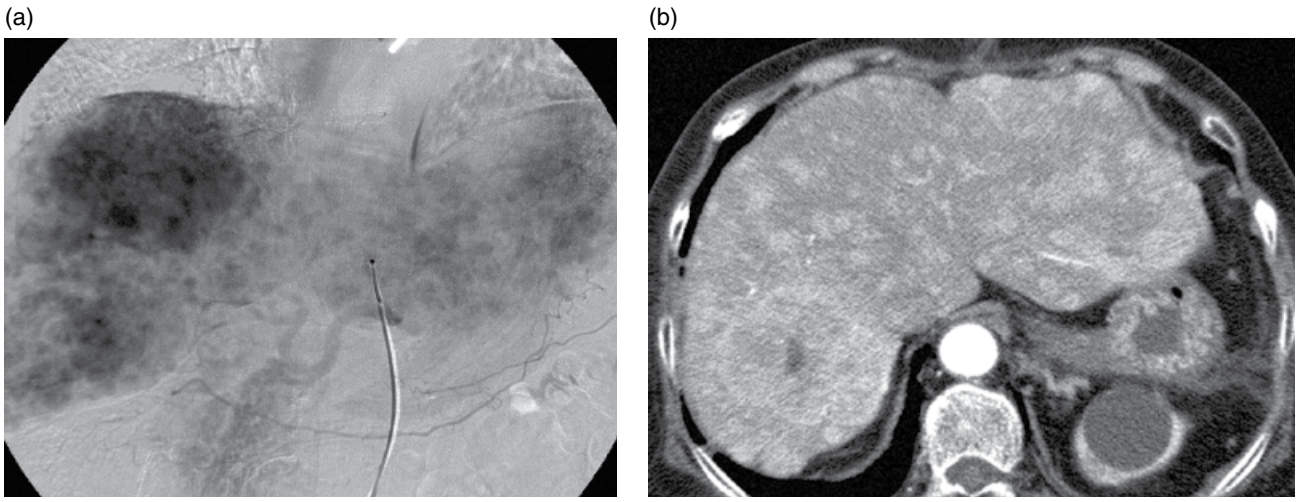

Figure 107.1 Staining of hepatic metastases during angiography. Results of tumor staining during angiography from the common hepatic artery (a) and computed tomography (b) in patients with multiple hepatic metastases from nonfunctioning pancreatic neuroendocrine tumor.

Table 107.1 Treatment indications for TAE/TACE of liver metastasis.

Guidelines	Treatment indication
ENETS	Functional PanNET
	Unresectable lesions with metastases in the liver or mostly in the liver
NCCN	Functional PanNET (unresectable and poor hormone control due to drug treatment)
	Well-differentiated PanNET with a large amount of intrahepatic tumor
NANETS	Unresectable and poor hormone control due to drug treatment

ENETS, European Neuroendocrine Tumor Society; NCCN, National Comprehensive Cancer Network; NANETS, North American Neuroendocrine Tumor Society; PanNET: pancreatic neuroendocrine tumor.

Selective internal radiation therapy (SIRT) is a novel treatment option in which radioactive microspheres containing β-ray source yttrium-90 (^{90}Y) are injected into the hepatic artery under fluoroscopy and directly irradiated from inside the tissue [7–9]. Radioembolization using ^{90}Y-lanreotide provides a radiologic response of 22.5–63% and median survival times of 22–70 months [7]. The regional concentration of chemotherapeutic drugs by TACE is reported to be 10–20 times higher than that by systemic chemotherapy; however, the additional effect of chemotherapeutic drugs on TAE alone remains unclear [2]. Repeat TAE/TACE would lead to the disruption of the arterial endothelium and then accelerate collateral formation, resulting in difficulty in future TAE/TACE.

Morbidity and mortality after TAE/TACE are reported to be 0–28% and 0–5.6%, respectively [2]. Complications in relation to TAE/TACE include hepatic abscess, hepatic dysfunction (sometimes hepatic failure arising from infarction), pleural effusion, gastric ulcer, and so forth. Many patients experience post-TAE/TACE syndrome symptoms, including transient fever elevation, leukocytosis, and increase in hepatic enzyme, most of which are observed within several days after TAE/TACE. Regional chronic infection in the biliary tree is a risk factor for hepatic abscess after TAE/TACE because the biliary system has a blood supply exclusively from a hepatic artery, and TAE/TACE would lead to biliary ischemia. Therefore, this technique should be avoided in patients who have a history of biliary intervention, including after pancreatoduodenectomy or endoscopic sphincterotomy. In addition, patients who have portal neoplastic thrombus or hepatic ascites are also contraindicated for TAE/TACE because of the high risk of post-TAE/TACE hepatic failure.

RFA

RFA can be performed during open surgery as well as laparoscopic operation, or by computed tomography or ultrasound-guided percutaneous techniques (Table 107.2). A previous report [10] demonstrated that RFA alone for hepatic metastases from well-differentiated PanNET can provide a favorable prognosis comparable to hepatic resection; however, the indicated cases were limited to patients who had a relatively small size and small number of metastatic lesions. At present, RFA is being performed

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 107.2 Surgical debulking using radiofrequency ablation for hepatic metastases from pancreatic neuroendocrine tumor. (a) Radiofrequency ablation using a tip device (arrow). (b) Completion of the debulking operation. Arrows indicate the trace of the tip device for radiofrequency ablation.

Table 107.2 Treatment indication of RFA for liver metastasis.

Guidelines	Treatment indication
ENETS	Unresectable liver metastasis that is localized or bilobed lesions used in combination with hepatectomy
NCCN	Liver metastasis (size 3 cm or less and four lesions or fewer)
NANETS	More useful than hepatectomy and TAE/TACE, performed in combination with resection and cryoablation

ENETS, European Neuroendocrine Tumor Society; NCCN, National Comprehensive Cancer Network; NANETS, North American Neuroendocrine Tumor Society; TAE/TACE, transarterial embolization/transarterial chemoembolization.

for persistent viable lesions as an adjuvant therapy during or after hepatic resection, or after TAE/TACE [3–9] (Figure 107.2). Adverse events related to RFA include pneumothorax, hepatic abscess, perforation of the gastrointestinal tract, skin burn, and so forth; however, major and fatal complications are rarely observed [7]. RFA for patients who have a history of biliary intervention should be avoided because of the same reason described above for TAE/TACE, where there is a risk of fatal hepatic abscess.

Use of RFA for primary PanNETs has been reported. An Italian group [11] reported their experience with 10 patients, with a mean tumor diameter of 16 mm (range 9–29 mm). All the lesions were completely ablated by the percutaneous route in seven patients, under laparotomy in two, and under laparoscopy in one. Mild pancreatitis occurred in three patients, all of whom were cured within ~2 days. No recurrence was observed during the median surveillance period of 30 months (range 12–60 months). Furthermore, a French group [12] reported transgastrointestinal endoscopic ultrasound-guided RFA ablation (EUS-RFA) for 14 PanNETs in 12 patients, with a mean tumor size of 13.1 mm (range 10–20 mm). All the lesions were safely ablated by this technique.

Although this intervention can be applicable for relatively small-sized primary PanNETs in patients who are in generally poor condition, further investigation using a larger study population and with long-term surveillance is needed to determine the adequacy of this procedure.

Enucleation of Benign, Neuroendocrine Tumors of the Pancreas

Frank Weber[1], *Andreas Machens*[2], *and Henning Dralle*[1]

[1] *Department of General, Visceral and Transplantation Surgery, Section of Endocrine Surgery, University Hospital Essen, Essen, Germany*
[2] *Department of Visceral, Vascular and Endocrine Surgery, Medical Faculty, Martin Luther University Halle-Wittenberg, Halle (Saale), Germany*

Introduction

The history of pancreatic surgery is closely connected to pancreatic neuroendocrine tumors (PanNETs), namely surgery for malignant and benign insulinoma [1,2]. Although not evidence based at the time, enucleation used to be preferred over resection because the endocrine tumor was almost always cured and the patient developed few and mostly minor surgical complications [3].

Some 90 years of surgical experience with small, clinically benign PanNETs later, the important role of enucleation is still uncontroversial. However, the growing number of pancreatic incidentalomas, unearthed by advanced imaging techniques [4–10], has multiplied the challenge of managing these tumors appropriately. Risk stratification, using proliferation markers such as frequency of mitosis and the Ki-67 index in the tumor [11–14], informs clinical treatment plans such that the therapy selected is commensurate with the risk profile of the tumor at hand. Interventions range from expectant observation in the absence of hormone excess to enucleation, and ultimately to pancreatic resection.

Observation Versus Surgery for Small Sporadic, Benign-Appearing, Nonfunctioning Pancreatic Neuroendocrine Tumors

Incidental small, nonfunctioning PanNETs feature less aggressive growth patterns on histopathology compared with symptomatic PanNETs [5]. Primary tumor size, reflecting a biological continuum, positively correlates with tumor grade [15], Ki-67 index [16], and the presence of lymph node and distant metastases [16–18]. The rate of lymph node metastases in nonfunctioning PanNETs smaller than 1 cm and up to 2 cm is estimated at 6.5% and 11.5% respectively. Therefore, these small tumors should not necessarily be considered indolent neoplasia [19]

For PanNETs smaller than 2 cm, disease-related mortality in most studies was close to zero [16,18–19]. Without surgical intervention, 13% [20] and 16% [16] of these sporadic nonfunctioning PanNET enlarged by more than 20%, yielding an estimated tumor growth of 0.12 mm per year [20]. In carefully selected groups of patients with nonfunctioning PanNETs who were managed without surgery, no disease progression was seen after 18 [20], 27 [21], and even 283 months [16]. Intriguingly, analysis of more than 2000 patients with nonfunctioning PanNETs revealed a survival benefit after resection of 1–2 cm (hazard ratio [HR] 0.37) and >2 cm (HR 0.3) large tumors but not after resection of tumors smaller than 1 cm (HR 2.81) [22].

Provided that there is no clinical evidence of metastases and tumor growth, sporadic, incidentally detected nonfunctioning PanNETs smaller than 15 mm may be candidates for expectant observation.

Preoperative Imaging and Assessment of Proliferative Tumor Activity

In patients with small PanNETs, preoperative imaging using endoscopic ultrasonography [23–26], cross-sectional (computed tomography [CT]; magnetic resonance imaging [MRI]) or functional (octreoscan; [^{18}F] fluoro-2-deoxy-d-glucose positron emission tomography [FDG-PET]/CT) imaging [27–31] informs the approach to the surgical target (laparoscopic versus conventional open surgery) and the method of tumor

clearance (enucleation versus pancreatic resection). Dual tracer scans based on ^{68}Ga-DOTATOC and ^{18F}FDG PET improve preoperative risk assessment further and should be considered for preoperative work-up [30,31].

Unlike nonfunctioning PanNETs, some functioning tumors, specifically very small insulinomas, may evade standard imaging. In this scenario, selective arterial stimulation is indicated to narrow down the location of the hormone-producing pancreatic tumor [32]. Small tumors residing in the anterior pancreatic head and the pancreatic body and tail usually qualify for enucleation unless they are situated deep down inside the pancreas and involve the main pancreatic duct (Table 108.1; Figs 108.1, 108.2, and 108.3). Conversely, deep-seated pancreatic tumors and tumors adherent to, or invading, the main pancreatic duct (see Figs 108.1 and 108.3) necessitate pancreatic resection, with partial or complete resection of the pancreatic head, body, or tail depending on the situation. Of note, preoperative imaging, whatever technique is being used, cannot exclude tumor involvement of the main pancreatic duct. Therefore, it is crucial in this setting that intraoperative ultrasonography be used to identify the pancreatic duct and to rule out multifocal lesions before deciding on whether to embark on enucleation or pancreatic resection [33].

Preoperative risk stratification is performed by endoscopic ultrasound-guided fine needle aspiration cytology to establish the diagnosis and allow tumor grading, supported by Ki-67 immunocytology to determine the proliferative tumor activity [33–36]. To make that determination correctly, the cytopathologist must be sufficiently experienced and cognizant of the methodologic limitations [34]. There is also a paucity of data about the prognostic significance of preoperative grading and Ki-67 immunocytology for small pancreatic tumors so that the benefits of enucleation versus pancreatic resection based on these findings remain unclear.

Table 108.1 Indications for enucleation of PanNET.

Small nonfunctioning PanNET 1–2 cm, or insulinomas up to 2 cm in greatest dimension and:
• benign appearing and low grade, based on standard and functional imaging, and, if performed, Ki-67 immunocytology
• without suspicious lymph node enlargement or distant metastases
• without wide and deep involvement of the pancreas
• without attachment to the main pancreatic duct on intraoperative ultrasonography.
Enucleation can be performed as a stand-alone procedure or in combination with pancreatic resection for multiple MEN 1-associated PanNET.
For PanNET located in the posterior head of the pancreas, both enucleation and head dorsal pancreatectomy may be considered.
Pancreatic gastrinomas should be treated preferentially by standard pancreatic resection irrespective of size because as many as 80–90% may be malignant and node positive.

Surgical Technique of Enucleation

Enucleation is the surgical technique of choice for small, benign-appearing or low-grade functioning and nonfunctioning PanNETs without clinical evidence of metastases or involvement of the main pancreatic duct [37–47]. Unless the tumor is situated in the posterior part of the pancreatic head [48,49], enucleation of tumors from the head, body, and tail of the pancreas is technically feasible. The key advantage of enucleation is reduced surgical trauma, with better postoperative

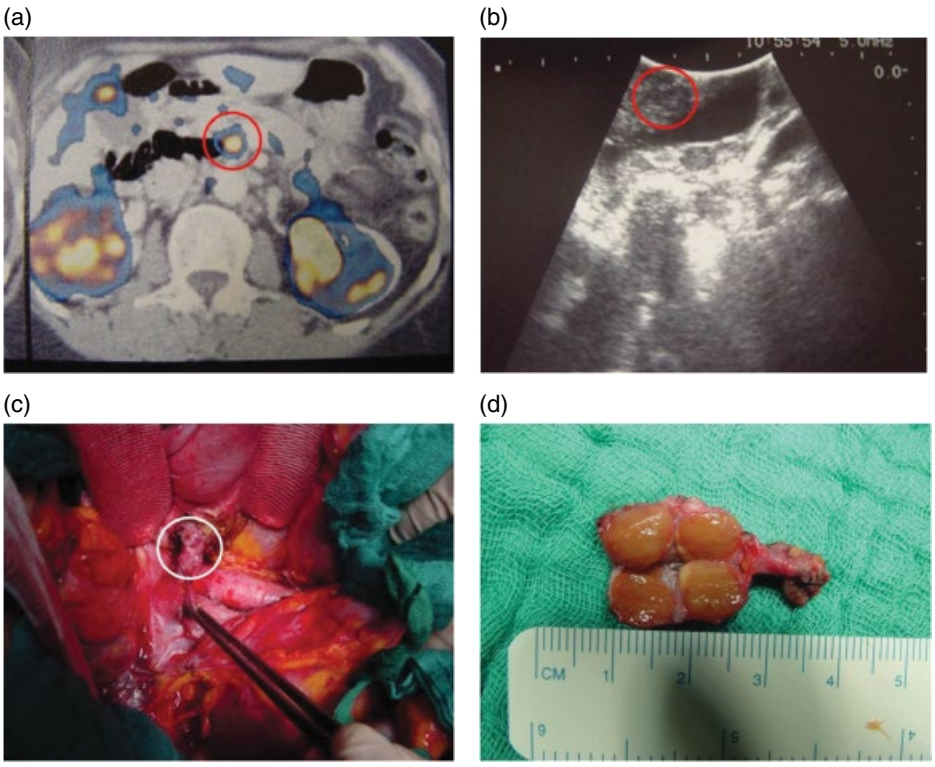

Figure 108.2 Enucleation of a multiple endocrine neoplasia type 1 (MEN 1)-associated insulinoma (encircled) in the uncinate process of the pancreas enucleated via open relaparotomy. (a) Preoperative ^{18}F-DOPA PET/CT; (b) intraoperative ultrasonography; (c) intraoperative view showing tumor enucleation; (d) surgical specimen.

endocrine and exocrine pancreatic function. Major disadvantages include the considerable risk of pancreatic fistula and the fairly low risk of late recurrence and metastases if pancreatic tumors should turn out to be malignant and no lymph node dissection was carried out at the time [49,50].

Enucleation of the PanNET is performed after ultrasonographic verification that the main pancreatic duct courses more than 2 mm away from the pancreatic tumor. There is curretnly inconclusive evidence as to whether preoperative stenting of the main pancreatic duct can enable deep pancreatic enucleation of larger tumors without jeopardizing surgical outcome [51].

Particular care must be taken to dissect the pancreatic parenchyma around the tumor capsule meticulously, without opening it or resecting adjacent pancreatic tissue (Figs 108.2 and 108.3). Great emphasis is laid on closing small pancreatic ducts and vessels using fine sutures or clips. Upon confirmation that the surgical margins of the enucleated tumor specimen are clear on frozen section, the pancreatic capsule is closed using atraumatic absorbable single or running 5-0 or 6-0 sutures. Surgical drains are routinely placed and subsequently removed depending on the amount of, and the enzyme concentrations in, the fluid drained. When the main pancreatic duct has been inadvertently opened, it may be safer not to attempt to over-sew the leak but to convert the planned enucleation into a segmental (pancreatic body) or distal (pancreatic tail) resection or fashion a Roux-en-Y jejunal loop onto the pancreatic defect to drain the leak [47].

Laparoscopic and robot-assisted techniques have become more popular in recent years and may evolve into a new routine for enucleation and distal pancreatectomy (Fig. 108.4) [52]. The placement of the port depends on the preoperative location of the tumor within the pancreas. Generally, a 12 mm supraumbilical port enables inspection of most lesions. Commonly energy devices are used for dissection. However, great care should be taken to heed the principles of open enucleation: careful identification of tumor margins and parenchyma-sparing dissection.

Short- and Long-Term Outcomes After Enucleation

Pancreatic enucleation is associated with a considerable rate of postoperative morbidity (48.1%) and Clavien–Dindo grade >3 complications (16%) [50]. A systematic

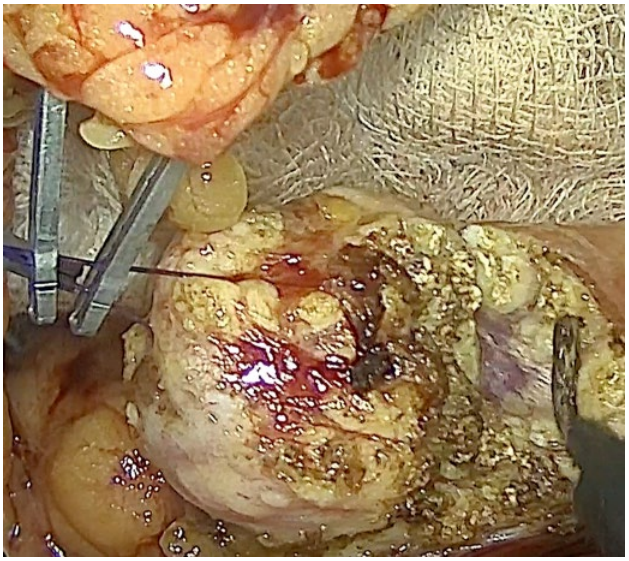

Figure 108.4 Laparoscopic enucleation of a 10 mm large, nonfunctioning neuroendocrine pancreatic tumor with a Ki-67 index of 3%. A transtumoral single stitch suture is used for traction to keep the line of resection close to the tumor capsule.

review and metaanalysis of enucleation versus standard pancreatic resection for small, mainly (69%) neuroendocrine tumors found that enucleation was superior to standard pancreatic resection, leading to shorter operations (P <0.001) with fewer blood loss incidents (P <0.001) [53]. In addition, enucleation was inferior regarding the overall fistula rate (33% versus 20%) but comparable in the length of hospitalization, postoperative mortality, and percentage of reoperation [53]. Other recent studies confirmed this observation [46,50,54]. Although the incidence of grade B/C pancreatic fistula was slightly higher after enucleation than after standard pancreatic resection (24.5% vs 14.0%), long-term outcome remained essentially the same [54]. Major contributors to postoperative pancreatic fistula included deep enucleations [39] and enucleation of PanNETs from the head and uncinate process of the pancreas [37,38], but not surgical (laparoscopic versus open) approach [39].

With respect to long-term oncologic outcome, enucleation was not inferior to standard pancreatic resection when the tumor was low grade, surgical margins were clear on definitive histopathology, and locoregional or distant metastases were absent [49,50,53,54]. After enucleation of <2 cm nonfunctioning PanNETs, late recurrences and metastases were found in 8% of patients [55].

The need to dissect regional lymph nodes in addition to clearing these tumors from the pancreas has sparked a lot of debate [56–59] because lymph node metastasis may have a negative prognostic impact on survival [54,57–59]. Among others, tumor size ≥2 cm, proximal location, and Ki-67 ≥3% are risk factors that predict LN positivity. However, lymph node metastases can be present in up to 25% of patients with nonfunctioning PanNETs, even in the absence of one or more of these risk factors [19,56,59]. Importantly, a recent muticenter study yielded comparable recurrence-free survival between node-positive and node-negative patients after removal of less than seven lymph nodes during distal pancreatoduodenectomy [59]. Preoperative identification of involved lymph nodes continues to be challenging [59], and concomitant lymph node dissection can drive up surgical morbidity.

Balancing the benefits against the risks, it becomes immediately apparent that the recommendation for or against lymph node dissection must be individualized considering the circumstances of each case. There is evidence to suggest that patients with small non-grade 1 tumors and clinically suspicious lymph nodes [19,58,59] benefit more from standard pancreatic resection and lymph node dissection than from enucleation alone. Otherwise, enucleation, preserving more pancreatic parenchyma, caused fewer endocrine (1% versus 11%) and exocrine (0% versus 25%) pancreatic failures than standard pancreatic resection [53].

Outcome After Laparoscopic Enucleation

The technical feasibility of laparoscopic and robot-assisted enucleation of PanNETs, alone or in conjunction with lymph node dissection, is well established, and both procedures are widely used [46,50,60–66]. In spite of this, prospective randomized controlled trials comparing laparoscopic with open enucleation have not been performed. Retrospective studies hint at a higher risk of pancreatic fistula after laparoscopic enucleation than laparoscopic resection without compromising overall outcome [54]. Enucleations of tumors from the pancreatic head are associated with more pancreatic leaks than left-sided enucleations [63], regardless of whether laparoscopic or conventional open enucleation has been carried out [65]. There is a dire need for more research, especially randomized controlled clinical trials, to clarify long-term oncologic and functional outcome (a) after open enucleation versus conventional pancreatic resection, and (b) after laparoscopic versus open pancreatic surgery.

Duodenum-Preserving Pancreatic Head Resection or Local Extirpation of Neuroendocrine Tumors of the Pancreas Larger than 2 cm

Takashi Hatori

Digestive Disease Center, International University of Health and Welfare, Mita Hospital, Tokyo, Japan

Background

An analysis of 35618 cases in the US Surveillance, Epidemiology, and End Results (SEER) database [1] revealed that the median age of onset for neuroendocrine neoplasms of the pancreas (PanNENs) ("neuroendocrine tumors" [NET] in the original paper) was 60 years; lesions were localized in the pancreas ("local") for 14% of patients, regional lesions ("regional") for 22% of patients, and distant metastasis ("distant") for 64% of patients. Regarding prognosis, the median survival time of localized cases was 136 months, whereas those of regional and distant cases were low, at 77 and 24 months, respectively. A 2017 analysis of the SEER database [2] reported that the total number of cases with neuroendocrine neoplasms (NENs) (NETs in the original paper) had greatly increased, with a particularly prominent increase in the number of localized and grade 1 (well-differentiated) cases. Considering the median survival time of PanNEN cases, localized cases had a survival of 230–240 months, regional cases had a survival of slightly less than 100 months, and distant cases had a survival of 20–30 months. Additionally, the extended survival times of localized and regional cases were reported. It is thought that early detection and treatment (surgical resection) of NENs led to improved diagnosis.

Imaging diagnosis is extremely important for diagnosing the progress of PanNENs and determining indications for resection. Dynamic computed tomography (CT), dynamic magnetic resonance imaging (MRI), endoscopic ultrasonography (EUS), and fine needle aspiration using EUS (EUS-FNA) are widely used for diagnosing the primary lesion. Thorough investigation of the presence of distant metastasis is also necessary, and dynamic MRI using gadolinium ethoxybenzyl diethylenetriamine pentaacetic acid (Gd-EOB-DTPA) is useful for diagnosing the number of localized liver metastases. Furthermore, somatostatin receptor scintigraphy (SRS) is excellent for the detection of extrahepatic metastases, such as bone metastasis, and fluorodeoxyglucose-positron emission tomography (FDG-PET) has also been reported to be useful for detecting the distant metastases of NETs, or NECs with high Ki-67 index values [3,4]. Additionally, ^{68}Ga-DOTATOC (gallium-68-DOTA [1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid] TOC [tri-octreotide])-positron emission tomography (PET)/CT has better image resolution than SRS and can favorably extract small lymph node or liver metastases, making it useful for detecting distant metastases [5,6]

Indications for surgical resection are determined based on these types of diagnostic imaging; however, for localized and regional PanNENs, resection is indicated for both functioning and nonfunctioning tumors, excluding a few cases. Among hereditary diseases, cases with multiple PanNENs with multiple endocrine neoplasia (MEN) type 1 complications are allowed to undergo follow-up observations until the tumor diameter reaches 2 cm (in the case of a nonfunctioning tumor) due to the young age of onset, and with the objective of avoiding total pancreatectomy.

The theme of this chapter is the surgical treatment of PanNETs over 2 cm; therefore, the main subject will be nonfunctioning PanNETs (well-differentiated grade 1–2), with descriptions provided regarding the treatment policy for small PanNETs.

Surgical Indication for Small Neuroendocrine Tumors of the Pancreas

The number of patients diagnosed with small, asymptomatic, nonfunctioning PanNETs around 20 mm increased along with the number of EUS and EUS-FNA cases. In response, it was debated whether all cases should be indicated for resection. In fact, investigating the follow-up observations of nonfunctioning PanNETs with sizes at or below 10 mm [7], 15 mm [8], or 20 mm [9] revealed only slight tumor growth, and there were no cases of lymph node or distant metastasis. Follow-up observations were first conducted on these cases, and it was reported that resection should be considered according to the increase in tumor diameter. Meanwhile, investigations that actively conducted pancreatectomy, including lymphadenectomy, reported that lymph node metastasis was observed at a certain frequency—even in PanNETs with a small tumor diameter [10,11]—warning against careless follow-up observations [12].

The National Comprehensive Cancer Network (NCCN) guidelines [13] indicate that even with a tumor diameter of 1–2 cm, there is a risk of lymph node metastasis; thus, they generally recommend enucleation with regional lymphadenectomy, or resection with regional lymphadenectomy. However, PanNETs that can undergo follow-up observations, i.e., those with tumor diameter <2 cm, low grade, incidental discovery, nonfunctional type, were divided between 12 weeks to 12 months, 1–10 years, and 10 years onwards according to resected cases. The European Neuroendocrine Tumor Society (ENETS) guidelines also indicate that when a major pancreatic resection is needed, follow-up observations are also allowed for asymptomatic, sporadic, nonfunctioning PanNETs smaller than 2 cm if minimal change is observed [14–17].

Local Extirpation of the Pancreas (Tumor Enucleation) and Parenchyma-sparing Local Resection

Pancreaticoduodenectomy (PD), a standard procedure for PanNETs of the pancreatic head, poses the risk of organ damage [18–22]; additionally, there is a risk of diabetes mellitus onset after distal pancreatectomy (DP), which is a standard procedure for PanNETs of the pancreatic tail [23]. Considering these risks, tumor enucleation and parenchyma-sparing local resection are useful options with respect to preserving organ function. The NCCN guidelines [13] state that tumor enucleation without lymphadenectomy, or parenchyma-sparing local resection (spleen-preserving DP, etc.), may be considered for insulinomas or nonfunctioning PanNETs smaller than 1 cm that are believed to have low risk of lymph node metastasis. However, as previously mentioned, it is important to fully recognize reports of positive cases of lymph node metastasis, even for nonfunctioning PanNETs smaller than 1 cm. The procedure should therefore be determined after sampling lymph nodes around the tumor during surgery, and confirming the absence of metastasis with rapid histology.

Furthermore, there are methods for tumor enucleation or parenchyma-sparing local resection where the endoscopic pancreatic duct stent is placed before surgery to prevent damage to the main pancreatic duct [24]. However, it has been reported that the risk of grade B+C postoperative pancreatic fistulas increases, and cases must be carefully selected [25].

Surgical Treatment of Neuroendocrine Tumors of the Pancreas Larger than 2 cm

The frequency of lymph node metastasis usually increases for tumors exceeding 2 cm; thus, standard pancreatectomy with regional lymphadenectomy (e.g., PD or DP/splenectomy) is recommended [13,17]. However, there are no data demonstrating that prophylactic lymphadenectomy improves the prognosis for PanNETs, and it is unlikely that lymphadenectomy procedures equivalent to regional lymphadenectomy for pancreatic ductal adenocarcinomas (PDAC) are uniformly conducted across all PanNETs larger than 2 cm in clinical practice.

It is currently believed that resection is conducted without excess or deficiency and includes the section suspected of metastasis via imaging. The objective of surgical resection is R0 resection, and it is thought that for the pancreatic head, avoiding pancreaticoduodenectomy accompanying multiorgan resection and selecting a procedure that preserves as much of the organs as possible—as long as radical cure is not impaired—will lead to improved quality of life in the patient. In that respect, duodenum-preserving total or subtotal pancreatic head resection (DPPHR), which can easily be combined with local lymphadenectomy in functional or nonfunctional PanNETs, including lymph nodes along the common hepatic artery, right of the portal vein/superior mesenteric vein and in the mesoduodenum up to the main trunk of the inferior pancreaticoduodenal artery, is thought to be a useful option regarding the frequency of postoperative complications and the preservation of pancreatic endocrine and exocrine function [20–22].

Duodenum-preserving Total or Partial Pancreatic Head Resection of Neuroendocrine Tumors of the Pancreas Larger than 2 cm

DPPHR comprises methods that include either complete or partial resection of the pancreatic head (Figure 109.1). Complete resection of the pancreatic head can be divided between methods that preserve or resect the common bile duct. Cases of common bile duct resection require reconstruction of the duodenum or jejunum and bile duct, in addition to pancreatic reconstruction (Figure 109.2). Cases of partial resection require pancreatic reconstruction of both the caudal pancreas and residual pancreatic head, including the common bile duct.

Three cases are described that underwent DPPHR for PanNETs with a tumor diameter over 2 cm; all cases underwent DPPHR with total resection of the pancreatic head. Case 1 describes a 40-year-old man with a nonfunctioning PanNET in the pancreatic head measuring 25 mm; after sampling the lymph nodes along the anterior pancreaticoduodenal vessels and confirming metastasis negativity, gallbladder/bile duct-preserving DPPHR was conducted (Figure 109.3). Pancreatic reconstruction was conducted by pancreaticojejunostomy, there were no early postoperative complications, and pathologic examination revealed PanNET G1. To date, the patient has survived for 14 years without recurrence, and no decreases in pancreatic endocrine and exocrine function were observed.

Case 2 describes a 50-year-old woman with a nonfunctioning PanNET in the pancreatic head measuring 23 mm; after sampling the lymph nodes along the anterior pancreaticoduodenal vessels and confirming metastasis negativity, DPPHR with cholecystectomy and bile duct resection was conducted (Figure 109.4). Bile duct reconstruction was conducted using biliary duodenal anastomosis, and pancreatic reconstruction was conducted using pancreaticojejunostomy; there were no early postoperative complications, and pathologic examinations revealed PanNET G1. To date, the patient has survived for 19 years without recurrence, and no decreases in pancreatic endocrine or exocrine functions were observed.

Case 3 describes a 60-year-old woman with a nonfunctioning PanNET adjacent to the superior mesenteric vein, measuring 30 mm from the lower part of the pancreatic head to the pancreatic uncinate. After sampling the lymph nodes along the superior mesenteric vein and artery near the tumor and confirming metastasis negativity, gallbladder/bile duct-preserving DPPHR was conducted (Figure 109.5). Pancreatic reconstruction was conducted via pancreaticojejunostomy, and there were no early postoperative complications. Pathologic examinations indicated PanNET G2 (Ki-67 index >3% [<5%]). Metastasis to the lymph nodes along the superior mesenteric vein and artery was observed eight years and two months later, and lymphadenectomy was conducted (Figure 109.6). Three years and one month later (11 years and three months after the initial surgery), multiple lymph node metastases were observed around the superior mesenteric artery, as well as around the stomach and aorta; drug treatment was therefore conducted.

DPPHR is excellent at preserving organ function, including pancreatic endocrine and exocrine function. However, since lymphadenectomy is insufficient for PanNETs over 2 cm, there is a need to carefully select cases, and indications are currently thought to be limited. The ENETS guidelines [17] indicate reduction surgery only when there are favorable conditions for maintaining

organ function; enucleation/local resection at surgery remains possible in many patients with PanNETs >2 cm, with pancreaticoduodenectomy reserved for selected cases. Factors other than tumor diameter need to be investigated to identify conditions where local extirpation or DPPHR for PanNETs over 2 cm may be indicated.

An investigation of the recurrence and survival of patients with nonfunctioning PanNETs following curative resection revealed that those with a Ki-67 index of 0–5% had a significantly more unfavorable recurrence rate within five years than patients with an index value of 6–20%. Multivariate analysis demonstrated that tumor diameter (>41 mm), lymph node metastasis, and Ki-67 index (>5%) were independent predictors of recurrence within five years [26]. Fujimori et al. also reported that patients with a Ki-67 index of less than 3% had a less favorable overall survival than patients with index values of 3–5%, 5.1–10%, 10.1–20%, and over 20% [27].

Therefore, it is believed that for PanNETs over 2 cm, DPPHR may be considered under the following conditions: Ki-67 index less than 3% and at least under 5% during preoperative EUS-FNA; lymph node metastasis not suspected on diagnostic imaging; no metastasis during sampling of lymph nodes near tumor during surgery; tumor diameter exceeds 2 cm, but only slightly and up to 25 mm; and organ preservation is expected. Furthermore, it may be possible to indicate DPPHR in

cases where multiple PanNETs are complicated with MEN 1, with maximum lesions exceeding 2 cm in the pancreatic head, and in cases of insulinomas—which are often benign—where the tumor larger than 2 cm is near the main pancreatic duct in the pancreatic head [13,17,28,29]. Nevertheless, in the Ki-67 index test, the concordance rate between EUS-FNA specimens and surgically resected specimens is typically around 72–74%. Therefore, including cases where the number of collected tumor cells is small or the tumor diameter is large may result in underestimation due to intratumoral heterogeneity; thus, a judgment must be made considering these factors [30–33].

Conclusion

DPPHR or local extirpation for PanNETs larger than 2 cm is thought to be limited regarding its indications due to the risk of lymph node metastasis. The following conditions are considered surgical options: Ki-67 index of 3–5% with EUS-FNA, no lymph node metastasis suspected with diagnostic imaging, no metastasis observed with sampling of lymph nodes near the tumor, tumor diameter of up to 25 mm, multiple PanNETs complicated with MEN 1 in the pancreatic head for the maximum lesion, insulinomas near the main pancreatic duct of the pancreatic head, and when the benefits of organ preservation can be expected.

Introduction

Pancreatic neuroendocrine tumors (pNETs) are rare neoplasms with an incidence of around 0.8/100 000 persons/year [1]. Nonfunctional pNETs (NF-pNETs) represent around 90% of all pNETs. They present clinical, radiologic, and molecular heterogeneity. Their origin can be sporadic or embedded in a genetic syndrome, mainly multiple endocrine neoplasia type 1 (MEN 1). They can be discovered as a localized stage or as metastatic disease. Nevertheless, NF-pNETs are more and more frequently diagnosed with a small size (<2 cm) and as incidentaloma. Their incidence over the last decades has been constantly increasing, mainly due to improvement in and wide diffusion of cross-sectional diagnostic imaging techniques, and some have reported an increased incidence of 710.4% in the last 22 years [2]. Consequently, most medical practitioners will be confronted with this type of neoplasm in their career.

Given the low-aggressive nature of NF-pNETs <2 cm, several management modalities can be discussed, depending on a delicate benefit–risk balance that remains debated. In this chapter, we will try to present all elements involved in the decision of surgical management of small NF-pNETs <2 cm, including indication, surgical principles, and long-term outcome, limiting our chapter to sporadic tumors.

Surgical Indications: The Controversy!

Surgical indication for NF-pNETs mainly depends on the oncologic risk of nodal and systemic dissemination, which remains one of the most important prognostic factors for pNETs [3]. Several studies have demonstrated the relationship between tumor size and aggressiveness of pNETs [4] and there is a well-documented relationship between NF-pNETs size and lymph node (LN) dissemination. Unlike NF-pNETs >2 cm, for which surgical indication is more consensual because of the significant risk of LN and distant metastases, the surgical indication for NF-pNETs <2 cm remains controversial. Indeed, given the low aggressiveness of these tumors, an active surveillance strategy can be discussed and should be balanced with the morbidity and functional consequences of pancreatic surgery.

Why Not Operate on a NF-pNET <2 cm?

Firstly, the risk of lymph node involvement in NF-pNETs <2 cm is considered to be relatively low in various studies and estimated at around 10%. Indeed, in a large and recent metaanalysis concerning 13 374 patients operated on for pNETs, the rate of LN involvement was around 11% for these small NF-pNETs <2 cm [5]. Furthermore, this risk of LN involvement can be even lower in selected patients considered to be at low risk: (i) with a tumor of 2 cm or smaller on preoperative imaging, (ii) with no bile or pancreatic duct dilation, (iii) being asymptomatic, (iv) with no enlarged lymph node or distant metastasis in imaging studies, and (v) WHO 2017 grade 1 [4,6]. In addition, the morbidity and mortality of pancreatic surgery are far from negligible. A study of the French national database of more than 22 000 patients undergoing pancreatic resection found that the overall postoperative mortality was 8.1% [7]. Additionally, postoperative morbidity was over 50% in the German ISGPS-based metaanalysis [8]. Thus, given the high morbidity and mortality of pancreatectomy, an initially nonsurgical

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.
© 2023 John Wiley & Sons Ltd. Published 2023 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/beger/thepancreas4e

strategy seems acceptable for selected patients at very low risk of LN involvement.

Additionally, the natural history of NF-pNETs <2 cm has been investigated and on follow-up of 34 months (still too short), neither tumor progression nor LN dissemination was observed [9]. Furthermore, the idea of operating on small and well-differentiated NF-pNETs, especially in young patients, to avoid the risk of tumor progression is nuanced by several data in the literature which suggest that there is no correlation between age and tumor aggressiveness [10]. According to these same authors, there is therefore an overtreatment of these tumors in young patients.

For all these reasons, a "watch and wait" strategy has been proposed and validated by the National Comprehensive Cancer Network (NCCN), the European Neuroendocrine Tumor Society (ENETS), and the European Society for Medical Oncology (ESMO) [11,12] for asymptomatic NF-pNETs <2 cm, grade 1 with neither signs of radiologic progression nor suspicion of LN involvement and distant metastases.

Why Operate on a NF-pNET <2 cm?

Nevertheless, this active surveillance strategy is still debated in the literature, with contradictory results. Indeed, in a SEER national database study of 263 NF-pNETs <2 cm [2], the rates of extrapancreatic extension, LN involvement, and distant metastases were ultimately higher, respectively 17.9%, 27.3%, and 9.1%. In addition, the five-year overall survival (OS) for these tumors was 85%. In a recent study of the national NCDB database, a multivariate analysis showed that patients with NF-pNETs of 1–2 cm had a better OS after surgery than those without surgery (hazard ratio [HR] 0.55; P <0.001) [13]. Similar results were found in the study by Sharpe et al. that concerned 380 patients with pNET <2 cm, in whom the risk of all-cause mortality was increased in the non-operated group compared to the operated group in multivariate analysis (HR 2.8; P = 0.0103) [14].

However, although the idea of an aggressive surgical strategy for small NF-pNETs is supported by several authors, the 2 cm cut-off is also debated. In a multicenter retrospective study, Dong et al. demonstrated that patients with small NF-pNETs had a higher risk of LN metastasis for tumor size 1.5–2 cm vs <1.5 cm (17.9% vs 8.7%; P = 0.015). They suggest the need to operate on patients with small NF-pNETs by performing systematic LN dissection for tumors over 1.5 cm [15]. In another multicenter retrospective study, a cut-off of 1.7 cm has also been proposed to predict the risk of malignancy with a sensitivity and specificity respectively of 92% and 75% [16].

In a recent systematic review and metaanalysis by Ricci et al. [17], even if the malignancy rate in sporadic and small pancreatic neuroendocrine neoplasms was lower than in large ones, for the authors this difference did not justify a "watch and wait" policy. They also pointed out several methodologic problems with the studies evaluating the "watch and wait" strategy, notably the retrospective nature of these studies with their inherent bias and the insufficient follow-up given the long life expectancy of these patients which prevents us from fully appreciating the true natural history of small NF-pNETs.

Moreover, in a recent study comparing the use of surgery and active surveillance in a population of asymptomatic NF-pNETs <2 cm, it was found that in clinical practice many parameters are taken into account in the decision to perform surgery in addition to those issued by international recommendations. These included patient preferences (32%), strong positivity at ^{18}FDG-PET/CT-scan (21.5%), young age of the patient (14.5%), and cytologically determined grade 2 tumors (14.5%) [18].

Finally, this conflicting literature highlights the difficulty in correctly standardizing the management of patients with NF-pNETs <2 cm and correctly distinguishing those who should be operated on from those who could be watched. It is also important to remember that any decision on the indication for surgery must take into account the patient's background and comorbidities and the type of surgery to be performed: pancreaticoduodenectomy vs distal pancreatectomy vs parenchyma-sparing pancreatectomy.

Summary

It remains to be determined whether NF-pNETs with "indolent" or "aggressive" behavior (since they cannot formally be called "benign" and "malignant") have a different, genetically unrelated carcinogenesis or if their progression follows the "adenoma–carcinoma sequence" and how to truly differentiate them [19]. What should be retained from this controversy is that if surgical resection is being considered for NF-pNETs <2 cm, a "watch and wait" strategy could be proposed in selected patients (i) with no bile or pancreatic duct dilation, (ii) who are asymptomatic, (iii) with no enlarged lymph node or distant metastases in imaging studies, (iv) WHO 2017 grade 1, (v) positive SRS imaging and negative ^{18}FDG-PET/CT-scan, (vi) candidate for pancreaticoduodenectomy, and/or (vii) with significant comorbidity. The most consensual cut-off is set at 2 cm.

A synthetic management algorithm is proposed to highlight the crucial elements involved in the discussion (Figure 110.1), and the factors that need to be taken into account are summarized in Table 110.1. Finally, there is no debate about the need to operate on patients with symptomatic NF-pNETs <2 cm or with suspected lymph node involvement. A prospective observational study,

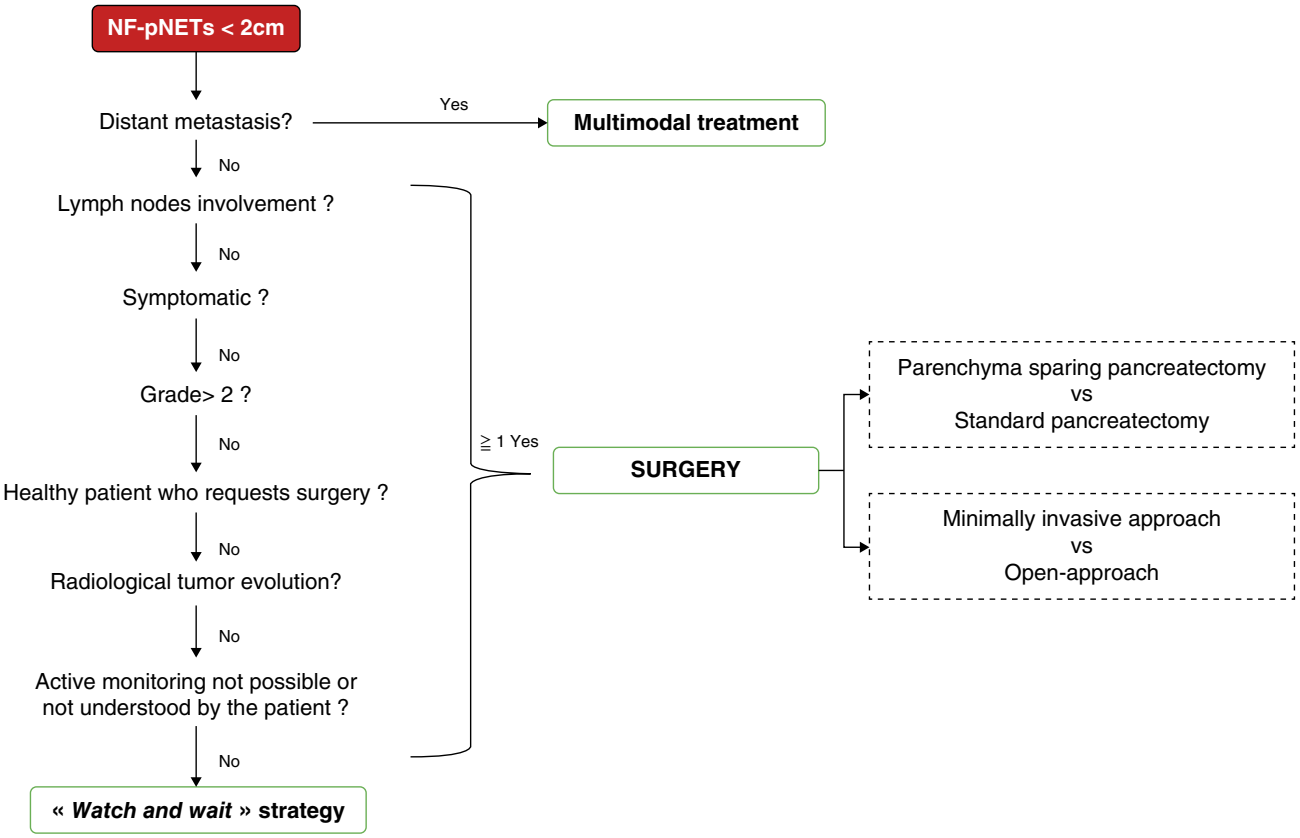

Figure 110.1 Algorithm for the therapeutic management of NF-pNETs <2 cm.

Table 110.1 Summary of the main arguments for the surgical approach and surveillance strategy for asymptomatic and well-differentiated NF-pNETs.

Why NOT operate on NF-pNETs <2 cm?	Why operate on NF-pNETs <2 cm?
High morbidity and mortality rates after pancreatectomy	Avoids excessive radiation from surveillance (especially in the young population)
Very low aggressiveness of these tumors according to retrospective studies	Definitive histologic evidence and better tumor staging (notably nodal involvement)
Low risk of lymph node involvement (<10%)	Benefit in terms of overall survival
Apparently, no relationship between age, disease duration, and tumor aggressiveness	The long-term natural history of these tumors is not well known
No clear argument in the literature to support a typical sequence: dysplasia–adenoma–carcinoma	

No ranking was made according to the importance of each argument.

the ASPEN study, is currently under way to better understand the natural history of asymptomatic NF-pNETS <2 cm and to provide more precision on the place of the "watch and wait" strategy [20].

Surgical Management

When surgery has been chosen for specific patients and tumors, the remaining questions are: when and how to operate?

Where Should Patients Be Operated On?

There is no doubt that the management of pNETs requires significant expertise. There is a consensus on the need to treat these patients in expert centers and this is particularly the case for pancreatic surgery in which the relationship between the volume of activity and postoperative outcomes has been extensively confirmed in the literature. For example, in the metaanalysis of Hata et al. involving 58 023 patients who underwent

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

pancreaticoduodenectomy, the postoperative mortality rate was significantly higher in low-volume centers than in high-volume centers (odds ratio [OR] 2.37; 95% confidence interval [CI] 1.95–2.88) [21]. In addition, in a retrospective study of 899 patients managed for gastroenteropancreatic neuroendocrine tumors, results showed a lower survival rate for patients treated in a low-volume hospital (HR 0.63; 95% CI 0.4–0.9) [22]. Lastly, the definition of a high-volume center is not consensual and varies between studies, but a reasonable threshold of >20–25 procedures per year seems acceptable [7,23].

What Kind of Surgery?

Choice Between Standard and Parenchyma-sparing Pancreatectomy

Pancreatic surgery can be divided into standard pancreatectomy (SP) and parenchyma-sparing pancreatectomy (PSP). SP includes pancreaticoduodenectomy (PD) for tumor localized in the head of the pancreas and distal pancreatectomy (DP) for tumor localized in the body and tail. Both allow resection with satisfactory oncologic criteria, i.e., lateral and deep margins while ensuring extensive lymphadenectomy. Nevertheless, they lead on the one hand to the resection of a significant part of the healthy pancreatic parenchyma, responsible for frequent endocrine and exocrine pancreatic insufficiencies in the long term, and on the other hand to significant morbidity and mortality in the short term [7,24].

Parenchyma-sparing pancreatectomy is a more conservative surgical approach that involves targeted resection of the tumor to minimize the sacrifice of pancreatic parenchyma. It includes central pancreatectomy (CP) for tumor localized on the isthmus, and enucleation, regardless of the location on the pancreatic gland, but usually in the head as an alternative to pancreaticoduodenectomy. Because of this more targeted resection, this approach avoids pancreatic insufficiency in the long term, but does not allow for formal lymph node dissection, but at best a peritumoral "cherry picking." It is therefore generally indicated for benign or low malignant potential tumors. In addition, CP has a high complication rate, notably postoperative pancreatic fistula (POPF) due to the existence of a pancreatic stump and a pancreatico-digestive anastomosis [25].

Finally, enucleation has usually a lower complication rate than the other pancreatectomies but can only be performed for tumors located more than 2–3 mm distant from the main pancreatic duct to avoid damage which would lead to a significant risk of POPF and the need to convert the surgery to a SP [26].

We therefore acknowledge that each of these techniques has advantages and disadvantages, summarized in Table 110.2, and which form the basis of

Table 110.2 Characteristics of the different pancreatectomy techniques.

		Pancreaticoduodenectomy [27–29]	Distal pancreatectomy [30–33]	Enucleation [26,30]	Central pancreatectomy [25,30]
Complications	Mortality[a]	3–5%	2%	1%	3–5%
	Overall morbidity	50%	30–50%	40–50%	60–70%
	POPF (grade B + C)[b]	20%	20–30%	20–40%	40%
	Endocrine pancreatic insufficiency [34]	10–20%	20–35%	<7%	2–5%
	Exocrine pancreatic insufficiency [35]	50–60%	10–30%	<3%	4–10%
Advantages		LND Bulk resection[c]	LND Bulk resection[c]	No pancreatic insufficiency	No pancreatic insufficiency
Disadvantage		Pancreatic insufficiencies Functional problems Bilio-digestive anastomosis[d]	Pancreatic insufficiencies Functional problems	No LND Only superficial tumor Risk of positive margins	No LND Many postoperative complications Risk of positive margins

[a] These numbers are for the expert centers. Mortality is more like 9.2% and 6.2% for PD and PD respectively outside expert centers [7].
[b] According to ISGPS 2017.
[c] Also allows the resection of other possibly associated pNETs in the same resection piece.
[d] Contraindicates certain therapies like arterial embolization in the context of liver neuroendocrine metastases [36].
LND, lymph node dissection; POPF, postoperative pancreatic fistula.

the discussion on the type of surgery indicated for NF-pNETs <2 cm.

Once a surgical indication has been decided, SP can technically be performed for all nonmetastatic NF-pNETs <2 cm. This is indicated when there is a doubt about preoperative LN invasion. Kasai et al. have proposed a preoperative risk stratification of lymph nodes metastasis for NF-pNETs based on tumor size, <50% cystic component and dilation of the main pancreatic duct to predict malignant potential and determine the necessity of LN dissection [37]. In DP, splenic preservation is possible if the tumor or metastatic LN does not invade the spleen or hilum, ideally with vessel resection (Warshaw procedure) to ensure adequate LN dissection.

Moreover, as discussed above, NF-pNETs <2 cm have a low risk of LN dissemination. It is therefore legitimate to propose a PSP when a surgical indication is considered [38], all the more if the patient is young and in good health, in whom the interest of avoiding long-term pancreatic insufficiency seems essential. However, in symptomatic NF-pNETs <2 cm, the feasibility of PSP (including enucleation) should be rediscussed according to the suspected risk of LN invasion.

There is some debate about the number of LN required on the resection specimen in the case where SP has been decided. According to studies, the number varies between 11 and 13, but by analogy with pancreatic adenocarcinoma, the most commonly accepted cut-off point is 12 LN removed [39]. Nevertheless, at least a lymph node picking should be done to assess N status.

Which Approach?

A minimally invasive approach (including laparoscopy and robot-assisted) has become the standard of care for many surgical procedures [40,41], reducing intraoperative blood loss, length of hospital stay and postoperative pain while ensuring a satisfactory oncologic outcome [42]. Nevertheless, its place in pancreatic surgery is not consensual [43].

In the case of PD, the laparoscopic approach is nowadays not recommended in routine practice. Indeed, a randomized controlled trial comparing laparoscopic vs open approach for PD was stopped prematurely because of excess mortality (10% vs 2%) [28]. In addition, some studies report on the robotic-assisted approach to PD and its value in performing anastomoses due to the three-dimensional vision and degrees of instrument mobility in all planes [29]. However, no recommendation has been defined yet to validate this approach in PD. This consideration can be extended to the central pancreatectomy that requires a pancreatic anastomosis.

In the case of DP, several trials, including randomized ones, report on the laparoscopic approach with satisfactory short-term results: shorter length of hospital stay, fewer severe complications, faster functional recovery, and less postoperative pain [32,33,43]. The laparoscopic approach seems to have at least equivalent results to the open approach in enucleation cases [30]. Systematic metaanalyses have produced encouraging results on the use of laparoscopy for pNETs [44] with a benefit of short-term postoperative outcomes. For these reasons, the ENETS recommendations consider that a minimally invasive approach could be proposed for DP, ensuring that the oncologic criteria are scrupulously respected (resection margins and quality of LN dissection if performed) [38]. This can be extended to enucleation that does not require a pancreatic anastomosis.

The Place of Surgery for NF-pNETs <2 cm in the Metastatic Context

The management of NF-pNETs <2 cm in the context of metastases can reasonably be done by analogy with publications evaluating the management of pNETs in the same context. The risk of metastasis at the time of diagnosis of NF-pNETs <2 cm is low in the literature, of the order of 9–10% of cases, and the preferred location is the liver as for all other pNETs [2]. Extrahepatic location is a contraindication to surgical resection due to the poor prognosis of these tumors [45]. The same applies to G3 pNETs with liver metastases for which the risk of recurrence is considered too high [38,46].

The management of NF-pNETs with synchronous metastases is conditioned by the resectability of the hepatic lesions. For patients with G1 or G2 NF-pNETs with resectable liver metastases, radical resection appears to be associated with increased disease-free survival, especially if it is a single metastasis (five-year disease-free survival: 100% for single metastasis and 51% for diffuse liver metastases) [47]. For patients with non-resectable liver metastases, primary resection of NF-pNETs seems controversial. In the case of a primary tumor located in the head of the pancreas, palliative resection of the pancreas employing PD seems unreasonable given the need to perform a biliary-digestive anastomosis which would contraindicate several medical therapies, notably chemoembolization [36]. In this case, and only if there is a local complication related to the tumor, other alternatives should be proposed (endoscopic drainage, gastroduodenal bypass, etc.) [46]. Nevertheless, for some patients with NF-pNETs G1 and G2 with tumor localized in the body or tail of the pancreas, resection of the primary tumor would appear to improve survival [38,46,48].

Long-term Outcomes and Follow-up

In the retrospective study of Assi et al. based on 2004 nonmetastatic well-differentiated NF-pNETs from the NCDB database, complete surgical resection provides a five-year OS rate of nearly 100%, 92%, and 89% for NF-pNETs <1 cm, 1–2 cm, and >2 cm respectively [49]. These OS rates are higher than in older studies (around 70% at five years), a difference that may be attributed to the initial presentation of these tumors which are diagnosed earlier. For small NF-pNETs, there does not appear to be any difference in OS between PSP and SP. Nevertheless, it cannot be denied that tumors resected by PSP had a more favorable clinical presentation, which obliges us to remain cautious about the interpretation of these results.

Moreover, in a recent metaanalysis, based on 2754 NF-pNETs operated on, the rate of disease recurrence was 21%, but this includes lesions over 2 cm. It was correlated with nodal metastases, tumor grade G2–3, microvascular invasion, and perineural invasion. However, no relationship was found between T stage, resection margins status, and disease recurrence. A scoring system has also been proposed to predict the rate of disease recurrence [50]. This would make it possible to better select patients at risk in order to offer personalized follow-up.

Long-term outcomes according to the type of surgery are mainly determined by the rate of endocrine and exocrine pancreatic insufficiencies (see Table 110.2). Thus, exocrine pancreatic insufficiency is maximal after pancreaticoduodenectomy (up to 60%) but almost absent after enucleation. It is an often misdiagnosed complication with a significant impact on quality of life [35]. The treatment is simple and based on supplementation with pancreatic enzyme. Regarding endocrine pancreatic insufficiency, there is a higher proportion of *de novo* diabetes after SP and especially after distal pancreatectomy (around 30%). This might be explained quite simply by the preferential distribution of β-cells and islets of Langerhans (responsible for insulin secretion) in the tail of the pancreas [51]. In a recent retrospective study of 268 patients operated on for pNETs (including 261 NF-pNETs) [34], the rate of postoperative diabetes (*de novo* or worsening of preexisting diabetes) was 21% and 7% for SP and PSP respectively. The authors demonstrated by multivariate analysis that postoperative diabetes was associated with a significant risk of tumor recurrence, independent of main prognostic factors and type of pancreatic surgery. This result is explained by the fact that diabetes mellitus has a known prooncogenic effect on some cancers, including pancreatic and gastrointestinal cancers [52].

Patients operated on for pNETs need long-term follow-up with clinical and biological (chromogranin A) checks and CT scan usually every six months. It is also reasonable to suggest that initially positive somatostatin receptor imaging (notably ^{68}Ga-DOTATOC PET/CT-scan) can be performed at baseline, and then every two years or in any doubtful situation. This prolonged follow-up is necessary because most recurrences occur after 5–10 years [11,38,46].

Conclusion

The management of pNETs and more specifically of small NF-pNETs (<2 cm) is particularly complex. It requires a multidisciplinary evaluation within expert centers with surgeons, gastroenterologists, oncologists, geneticists, radiologists, and pathologists. For NF-pNETs <2 cm, two options can be considered: a "watch and wait" strategy or a surgical resection. The choice between SP with LN dissection and PSP depends on the characteristics of the tumor, the presence of preoperative LN invasion, and the patient's condition. The laparoscopic approach is commonly accepted and encouraged except for PD. In selected patients, it is possible to propose a "watch and wait" strategy, but it is important to remember that long-term data are still lacking for this strategy.

Introduction

Over the past two decades, pancreatic neuroendocrine tumors (PanNET) in general, not just small tumors <2 cm in greatest dimension, have become more frequent worldwide [1–8]. Among large PanNET, 90% of tumors are nonfunctioning [2], and about 40% have spread to distant organs at the time of diagnosis [8]. Whereas patient age is by and large comparable in patients with small and large sporadic tumors, greater primary tumor size correlates positively with lymph node and distant metastases, lower histopathologic grading, and extrapancreatic extension [1,5–9] Although resection of the primary tumor, even when metastases are present, may prolong survival, the considerable morbidity inherent in major pancreatic resection limits the net benefit of extended surgery for locally advanced and metastasized PanNET [10–13].

Clinical Work-up of Advanced PanNET for Major Oncologic Resection

Unlike functional PanNETs that present with signs and symptoms of hormone excess, such as insulinoma, gastrinoma, and the rare glucagonoma, vasoactive intestinal peptide-releasing tumor (VIPoma), or somatostatinoma, nonfunctioning PanNETs manifest with symptoms caused by tumor expansion, invasion, or metastatic disease. Nonfunctioning PanNETs often reside in the pancreatic head, mimicking pancreatic adenocarcinoma, and compress adjacent organs, giving rise to jaundice, abdominal pain, weight loss, nausea and vomiting, back pain, and occasionally pancreatitis [2]. About 10% of PanNETs are inherited in the context of multiple endocrine neoplasia type 1 (MEN 1), von Hippel–Lindau syndrome (VHL), neurofibromatosis type 1 (NF1), and the tuberous sclerosis complex (TSC). Patients with hereditary PanNET typically are younger than patients with sporadic PanNET, have multiple lesions scattered throughout the pancreas, and often yield a positive family history. MEN 1-associated PanNET often comprises functioning and nonfunctioning tumors [14,15], necessitating more customized treatment plans than are required for solitary sporadic PanNET (Fig. 111.1) [16,17].

Diagnosis and extent of PanNET are established by cross-sectional (computed tomography [CT]; magnetic resonance imaging [MRI]) [18–20] and functional imaging (somatostatin receptor scintigraphy) in conjunction with [^{18}F]fluoro-2-deoxy-d-glucose positron emission tomography (FDG-PET) [21,22] and percutaneous or endoscopic ultrasound (EUS)-guided biopsy [23–26]. Because treatment concepts for metastatic exocrine and endocrine cancers differ tremendously, biopsy of the primary tumor or its metastasis takes center stage in differentiating pancreatic adenocarcinoma from PanNET. Clinical staging and grading of the PanNET afford stratification of patients into prognostic subgroups and facilitate individualized treatment concepts [27–29]. Ki-67 immunocytology, using World Health Organization (WHO)-defined categories of 0–3% (grade 1), 3–20% (grade 2), and >20% (grade 3) [30], helps estimate the patient's risk of recurrence and survival [3,7,31–33].

The separation of neuroendocrine cancers (NECs) from highly proliferative, well-differentiated NETs prompted calls for biomarkers that distinguish NECs

from G3 NETs because the latter, unlike the former, typically qualify for major oncologic resection [30]. For WHO grades 1, 2, and 3, five-year overall survival has been estimated at 77%, 63%, and 20%, respectively [8]. With a Ki-67 score of <2%, the likelihood is remote that the cancer extends beyond the pancreas, invades great vessels, is metastatic, or will recur [3,31]. Most studies support the notion that poor tumor differentiation, WHO grade 3, and distant metastases are closely connected to PanNET-specific mortality [31,34–39].

Surgical Approach to Locally Advanced Nonfunctioning PanNET Without Clinical Evidence of Distant Metastases

Based on preoperative imaging and intraoperative exploration, locally advanced nonfunctioning PanNETs are defined as large tumors frequently invading parapancreatic organs such as the stomach, spleen, colon, kidney, or adrenal gland, and/or great vessels, namely the mesentericoportal vein, superior mesenteric artery, or celiac

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. trunk. Lymph node metastases may evade imaging [40,41] but if clinically apparent, often herald systemic disease. As positive lymph nodes have been identified as a risk factor for early recurrence [42], regional lymph node dissection has become an integral element of surgery for advanced disease.

Given the unavailability of equally effective nonsurgical treatment options, resection of a locally advanced nonfunctioning PanNET at institutions experienced in pancreatic surgery is the method of choice [11–13,32,40]. Provided that clear surgical margins are achievable, resection of neighboring organs and great vessels seems worthwhile [39,40]. Multivisceral resection of advanced (pT3/pT4) PanNETs frequently includes the spleen (>70%) but also major vessels (17%), stomach (4%), bowel (2%), and kidney (2%) [11]. Retrospective data suggest that complication rates after multivisceral resection are comparable to those after standard surgery [43]. Resection of the mesentericoportal axis is almost always feasible (Fig. 111.2) and requires only rarely the use of an autologous vein, or prosthetic material for reconstruction [44–50]. Although it has been shown not to increase surgical morbidity in patients with PanNET, macrovascular venous invasion is associated with significantly worse median overall survival (60 vs 149 months) [51].

Conversely, arterial resection and reconstruction (Figs 111.3, 111.4, and 111.5) are much more complex [52–56] and entail incremental surgical morbidity and mortality [57,58]. The decision to embark on resection of great arteries needs to be pondered carefully, taking into account patient age and comorbidity, stage and grade of the PanNET, extent of tumor invasion of the artery (celiac/hepatic artery and/or superior mesenteric artery without or with invasion of the mesentericoportal vein), and the condition of the artery itself (presence or absence of arteriosclerosis). However, systematic clinical

outcome studies after resection and reconstruction of one, two, or more major vessels invaded by PanNET (see Fig. 111.5) are unavailable because of the rarity of the condition [52,54].

In the absence of evidence-based information, best judgment should be exercised to determine, on a highly selective basis, whether to resect major arteries invaded by nonfunctioning locally advanced PanNET. Importantly, recent data indicate that pancreatic surgery for large PanNET does not improve cancer-specific survival in patients aged 80 or older, nor in patients aged 70 or older who harbored small (<20 mm) primary tumors [59].

A number of studies have explored the effectiveness of neoadjuvant therapies for locally advanced and metastatic PanNETs [60]. These treatments included various combinations of capecitabine/temozolomide or streptozotocin/5-fluorouracil, which produced partial responses and tumor shrinkage [61–63]. Other studies that evaluated the feasibility of neoadjuvant peptide receptor therapy significantly reduced tumor size and enabled resection of previously unresectable primary tumors in up to one-quarter of patients [64,65].

To clarify resectability, the greatest tumor extension outside the pancreas needs to be explored first. For invasion of the mesentericoportal axis below the pancreas, the infrapancreatic/infracolonic approach (Fig. 111.6) is a natural choice. When major branches of the superior mesenteric vein are invaded, complete resection of the tumor is unfeasible and should not be attempted. Major arteries invaded by tumor, such as the superior mesenteric or hepatic artery, are best resected toward the end of pancreatic surgery to allow immediate arterial reconstruction, keeping ischemia time to a minimum. Arterial reconstruction is accomplished directly, or with the use of autologous or prosthetic material. Resection of the splenic vein alone does not warrant reconstruction [66]. In one study, segmental portal hypertension was not associated with increased mortality or severe morbidity after surgery for advanced PanNET [67].

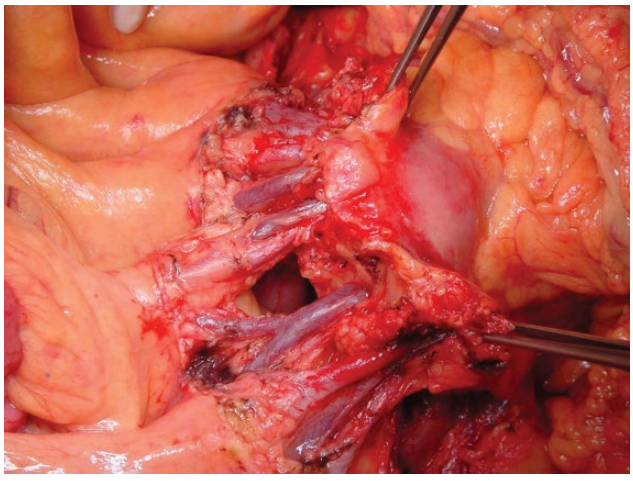

Figure 111.6 Infracolonic dissection of the superior mesenteric vein and its branches, fenestrating the transverse mesocolon to gain access to a locally advanced PanNET of the pancreatic head.

Locally Advanced Nonfunctioning PanNET with Clinical Evidence of Distant Metastases

Larger primary PanNET are often associated not only with invasion of adjacent organs and major vessels and more frequent lymph node metastasis, but also with liver metastases [7]. Extensive surgery for locally advanced PanNETs with liver metastases, even though it may prolong survival, is controversial regardless of whether the metastases are resectable or not [68–73]. Clinically, PanNETs present in more than 50% of patients with liver metastases as the only systemic manifestation, which are unresectable in 80% of patients [68].

For locally advanced PanNETs without or with liver metastasis alone, or with liver metastasis as only one manifestation of systemic disease, there are no systematic outcome studies regarding the benefit of resection of the primary tumor so that the role of surgery remains to be defined for a wide range of clinical settings: symptomatic versus asymptomatic PanNET, with or without liver or other remote resectable or unresectable metastases; number and size of liver metastases; location of the primary tumor within the pancreas (head versus body or tail); and tumor grade and differentiation.

In light of the current literature, and subject to interdisciplinary consensus taking into account the circumstances of the case, it may be reasonable to suggest the following courses of action.

- For patients with *locally advanced PanNETs with resectable liver metastases*, resection of the primary tumor should be considered, especially when the tumor is symptomatic [39]. The issue of whether liver resection should take place in the same surgical session or whether a staged approach should rather be pursued depends on the extent of resection and the patient's condition [69,71]. A recent metaanalysis found that liver resection improved symptom relief and survival compared with nonsurgical therapy [72].
- Patients with *unresectable liver metastases of locally advanced PanNETs* also may benefit from resection of the primary tumor. In a single-center study of

43 patients with PanNET and unresectable liver metastasis, the five-year disease-specific survival was 82% in the operative group compared with 50% in the nonsurgical group (P = 0.027). On multivariate analysis, not only removal of the primary tumor but also younger patient age, a lower Ki-67 index, and a liver tumor burden <25% were associated with better disease-specific survival [68].

- Patients with *locally advanced PanNET and liver metastases as only one manifestation of systemic disease* are candidates for surgery only in exceptional circumstances, even when the liver metastases should be resectable. In these highly selected patients, the limited clinical effects of resection need to be carefully balanced with the benefits of nonsurgical treatment options [39,74,75].

Introduction

Insulinoma is the most common functional neuroendocrine neoplasm (NEN) [1–5]. As symptoms of hyperinsulinemic hypoglycemia are varied and nonspecific, diagnosis of insulinoma is sometimes difficult. Therefore, a cautious diagnostic approach is taken to detect the presence of insulinoma and localize the tumors [1,2,5]. Most insulinomas are benign, and surgical resection can bring about complete cure. However, in incurable cases, hormonal symptoms are difficult to control, requiring multidisciplinary therapy tailored to each patient [1,3–5].

Clinical Features of Insulinomas

Insulinoma is a very rare disease, developing in 1–32 individuals per 1 million population a year [1–4]. Insulinoma presents characteristically in the fifth decade of life, and has a predilection for women (41% male and 59% female) [2,4]. Among functional NENs, insulinomas occur most frequently. Over 99% of insulinomas occur in the pancreas [1–3]. The majority of these tumors are sporadic, solitary, and small in size (≤2.0 cm) [2,4]; 4–12% of cases are associated with multiple endocrine neoplasia type 1 (ME1), and ME1-associated insulinomas are often multiple [6–9]. About 90% of insulinoma are benign, and surgical resection can bring about complete cure [1–3,6]. The remaining 10% are malignant insulinomas with distant metastasis at the time of diagnosis; the five-year relative survival rate is 55.6% [1,3,10,11].

Hypoglycemic symptoms in insulinomas are divided into two major categories: neuroglycopenic symptoms, such as confusion, visual changes, amnesia, and coma; and adrenergic symptoms, such as sweating, weakness, and tremors (Table 112.1) [4,9,12,13]. Hypoglycemic symptoms occur most frequently in the fasting state but they may occur in both fasting and postprandial state in 18–21% of patients, and only postprandial in 6% [1,13].

The classic diagnosis of insulinoma is via Whipple's triad (presence of hypoglycemic symptoms, blood glucose level under 50 mg/dL at the time of symptom onset, improvement of symptoms after glucose intake) [1,2,4,5]. Although insulinoma is the most frequent cause of adult hypoglycemia, there are other various hypoglycemia-causing diseases that require differentiation, and therefore cautious diagnosis is important [2,4,7–9].

Diagnosis of Insulinomas

When excessive endogenous insulin secretion is observed during hypoglycemia, insulinoma should be suspected [1,4,5,11,14]. When spontaneous hypoglycemia is observed, blood is drawn to measure plasma glucose (PG), serum levels of immunoreactive insulin (IRI), proinsulin, C-peptide, and β-hydroxybutyrate (BHOB) [13–19]. According to the United States Endocrine Society Clinical Practice Guideline, the diagnosis of insulinoma is confirmed by hypoglycemic symptoms and the following six diagnostic criteria [1]: (i) plasma glucose levels ≤3.0 mmol/L (≤50 mg/dL), (ii) insulin levels ≥3.0 μU/mL (≥18 pmol/L), (iii) C-peptide levels ≥0.6 ng/mL (0.2 nmol/L), (iv) proinsulin levels ≥5.0 pmol/L, (v) BHOB levels ≤2.7 mmol/L, and (vi) an increase in plasma glucose 1.4 mmol/L (≥25 mg/dL) after IV glucagon. When spontaneous hypoglycemia is not

Table 112.1 Clinical symptoms and frequencies in patients with insulinoma.

Symptoms	Frequency (%)
Neuroglycopenic symptoms	
Confusion	67–80
Visual changes	42–59
Amnesia or coma	47
Altered consciousness	16–38
Seizures	16–17
Headache	7
Adrenergic symptoms	
Sweating	30–69
Weakness	28–56
Tremors	12–24
Hyperphasia	14
Palpitations	5–12
Anxiety	12
Obesity	<50

Data adapted from references Adapted from [6,23].

observed, the following tolerance tests are conducted to induce hypoglycemia, and the above parameters are measured.

Fasting Test (Table 112.2)

The 72-hour fasting test is the gold standard for the diagnosis of insulinoma [1–5,7,9,13,20]. In recent years, various insulin surrogates have become measurable, and some reports have indicated that the fasting period can be shortened to 48 hours [17,21]. For the fasting test, a patient needs to be hospitalized for blood collection every 4–8 hours under close medical supervision, for measurement of PG, IRI, proinsulin, and C-peptide [1,2,18–21]. PG ≤45 mg/dL with hypoglycemic symptoms is considered as a positive response. Positive results are obtained within 12 hours in 33–42.5%, within 24 hours in 65–66.9%, within 48 hours in 93–94.5%, and within 72 hours in 98.4–99% [17,20]. As hypoglycemic symptoms are often unnoticeable in patients with insulinoma, those symptoms should not be overlooked [17,22]. After the fasting test, serum levels of BHOB and free fatty acid are measured as supplementary data [15–17,21].

In rare insulinoma cases, positive results are not produced in the fasting test, and insulin is excessively secreted in response to glucagon or glucose loading, according to previous reports [21,23,24]. After the fasting test, glucagon 1.0 mg is intravenously injected, and PG is measured at 10, 20, and 30 minutes.

Table 112.2 Fasting test instructions.

1) Meal is eaten at 18:00, and the fasting test is started.
   - Medication is minimized, and unnecessary medicines are suspended.
   - No-calorie decaffeinated drinks can be taken.
   - The patient is instructed to engage in daily activities.
2) Blood is drawn every 6 hours.
   - Blood tests include plasma glucose (PG), immunoreactive insulin and C-peptide.
   - After PG is lowered to 60 mg/dL or below, blood is drawn every 1–2 hours.
3) Judgment is made as to whether the fasting test should be terminated.
   - PG ≤45 mg/dL and emergence of hypoglycemic symptoms are taken as a positive result for the fasting test, and the test is terminated.
   - When the result is negative, the test is terminated at 72 hours.
   - As PG ≤45 mg/dL may occur during fasting in healthy people (females in particular), the test should not be terminated only with PG decrease.
   - Even if PG ≤45 mg/dL is not achieved, the test can be terminated if hypoglycemic symptoms are severe. In such cases, the succeeding blood tests are carried out.
4) The following blood examinations are conducted at the end of the fasting test.
   - β-hydroxybutyrate and free fatty acid are measured.
   - Glucagon 1.0 mg is intravenously injected, and PG measurements are taken at 10, 20, and 30 minutes.
   - ΔPG = PG(max)−PG (baseline) is calculated to determine the response to glucagon.

   When insulin autoantibody syndrome is suspected, antiinsulin antibody and antiinsulin receptor antibody levels are measured.
5) Blood glucose level is promptly corrected after the test.

When ΔPG, defined as the difference between the maximum and baseline levels, is ≥25 mg/dL, insulinoma may be considered [1,15,21].

Mixed Meal Tolerance Test

Some insulinoma patients present with hypoglycemic symptoms only in the postprandial state [1,13]. Furthermore, it is important to differentiate noninsulinoma pancreatogenous hypoglycemia syndrome (NIPHS) from insulinoma. As hypoglycemia often occurs after meal intake in NIPHS, it is important to carry out a mixed meal tolerance test [18,25]. In this test, fasting starts the night before the test, and the mixed meal tolerance test begins at breakfast. The meal consists of the items that are likely to induce hypoglycemia, or a commercially available mixed meal is used. Since reactive hypoglycemia often occurs over five hours after meal intake, observation is continued until five hours after the start of test [18,26].

Localization of Insulinomas

In typical cases of insulinoma, the tumor is well vascularized and has a well-defined border. Its image is most enhanced in the arterial phase in dynamic CT imaging (Fig. 112.1) [27,28]. On magnetic resonance imaging (MRI), insulinomas generally show low signal intensity on fat-suppressed T1-weighted images and high signal intensity on T2-weighted images [27,28]. As the size of the insulinoma is small (under 2.0 cm) in 80%, and MEN 1-associated insulinoma often occurs at multiple sites, it is difficult to identify all tumors with conventional imaging [1,7–9,29]. The sensitivities of dynamic computed tomography (CT) and MRI are 45–63% and 54–85%, respectively [28–30]. The diagnostic ability of these tests is not sufficient, so these modalities are combined with

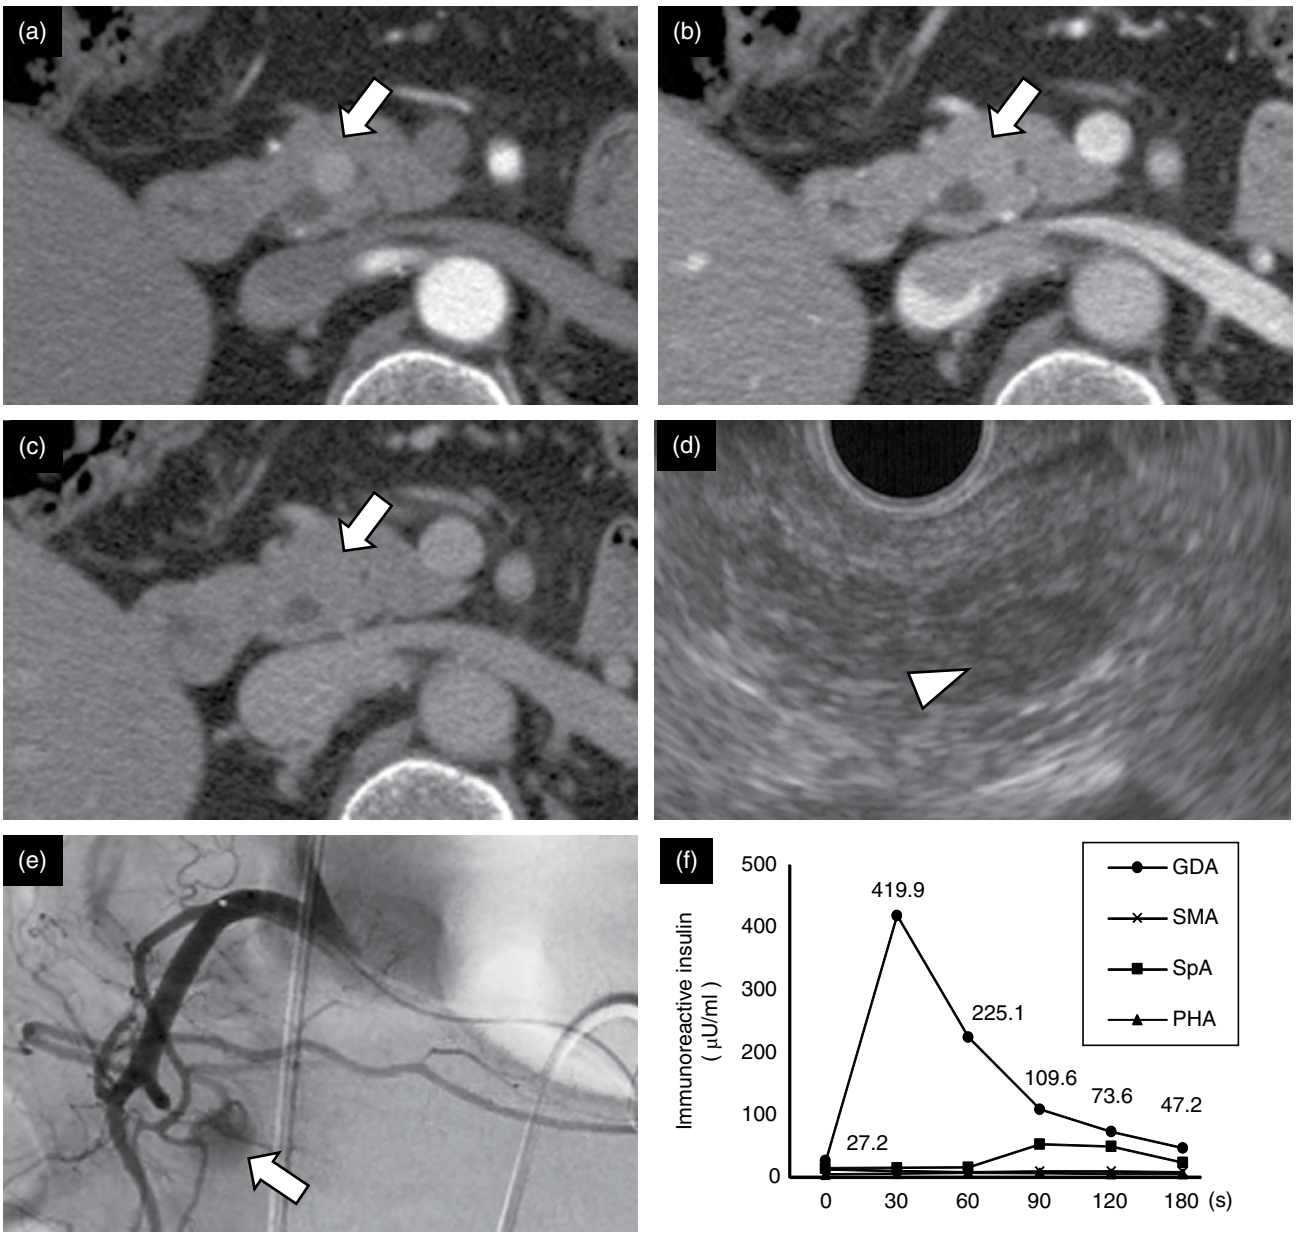

Figure 112.1 A 68-year-old woman with insulinoma at the pancreatic head. Abdominal CT imaging (a–c) shows an oval lesion with regular margins and well-defined borders, which is most enhanced in the early phase. The lesion cannot be identified in the portal phase/late phase (arrow). (d) EUS shows an oval hypoechoic mass with regular margins and well-defined borders (arrowhead). In the SACI test (e,f), a tumor is shown by gastroduodenal artery imaging, and the insulin level is markedly stepped up by GDA. The tumor localization by SACI test coincided with imaging findings.

endoscopic ultrasonography (EUS), selective arterial calcium injection (SACI) test, and molecular imaging [1–4,14].

Endoscopic Ultrasonography

On EUS, insulinoma appears as an oval hypoechoic mass with a well-defined border; on color/power Doppler, it appears as a hypervascular pattern (see Fig. 112.1) [29,31,32]. Due to its high sensitivity (80–94%), EUS is more useful for localization of tumors, compared with CT or MRI [2,29,31,32]. EUS is especially effective for detection of small insulinomas, and when the size of the insulinoma is 12 mm or smaller, EUS is significantly superior to CT imaging [31].

Selective Arterial Calcium Injection (SACI) Test

The SACI test is useful when a tumor cannot be confirmed by other modalities (occult insulinoma) [1,5,33,34]. It is also useful in identifying insulinomas from among multiple pancreatic tumor masses in a MEN 1-associated case. For abdominal arterial angiography, calcium gluconate (0.025 mEq/kg) is injected from the feeding artery for each pancreatic region (gastroduodenal artery, superior mesenteric artery, splenic artery, etc.), and then IRI in hepatic venous blood is measured. Based on the increase in IRI, the location of insulinoma is determined (see Fig. 112.1) [33,34]. IRI is measured at baseline, 30, 60, 90, and 120 seconds, and a twofold or higher increase in IRI over baseline is considered positive. Sensitivity of SACI test for insulinoma is 82.2–100% and it produces excellent results [33,34].

Molecular Imaging (Scintigraphy, SPECT, PET/CT)

As the proliferative ability of insulinoma is low, ^{18}F-FDG PET/CT imaging of insulinomas is disappointing [1,30,35]. While ^{68}Ga-DOTATOC PET/CT, ^{111}In-pentetreotide scintigraphy, and SPECT are carried out for somatostatin receptor imaging, the expression rate of somatostatin receptor 2a is low in benign insulinomas, with a low positivity rate and sensitivity below 50% [29,30,35]. Meanwhile, the glucose-like peptide 1 (GLP-1) receptor is known to be highly expressed in more than 90% of insulinoma cases. Therefore, GLP-1 receptor imaging is considered useful[29,30,35-37].

To improve imaging of insulinomas, radiolabeled GLP-1R analogues for SPECT/CT imaging, such as ^{111}In-DOTA-exendin-4, ^{111}In-DTPA-exendin-4, and ^{99m}Tc-HYNIC-exendin-4, have been developed and evaluated in patients [29]. In recent reports, GLP-1 receptor SPECT/CT had 95–100% sensitivity [29]. In patients with occult insulinoma, ^{68}Ga-DOTA-exendin-4 PET/CT is superior to ^{111}In-DOTA-exendin-4 SPECT/CT [36].

Treatment of Insulinomas

Treatment of insulinomas can be divided into two categories: treatment of symptomatic hypoglycemia caused by excessive insulin secretion, and treatment of the tumor itself. Therefore, in treating insulinomas, hormone symptoms should be well controlled, while the tumor is simultaneously treated [1,3,5].

Treatment of Symptomatic Hypoglycemia

Firstly, small, frequent meals or oral/intravenous glucose supplementation is given [1,3,38]. As for medical therapy, diazoxide (50–300 mg/day, increasing up to 600 mg/day) is most useful [1,3,9]. Diazoxide directly acts on pancreatic β-cells, suppressing insulin secretion and thus improving hypoglycemic symptoms. Several days are required for stabilizing blood glucose, while edema, weight increase, deterioration of renal function, and hirsutism may occur as adverse reactions [1,3,4,13]. Other drugs such as glucocorticoids and glucagon injections are effective, according to some reports [3,13].

Somatostatin analogues, such as octreotide, pasireotide, and lanreotide, were effective for improving hypoglycemic symptoms in 35–50% of insulinoma cases [1,3,5]. The effects of somatostatin analogues depend upon the expression of somatostatin receptor subtypes 2, 3, and 5. Therefore, in cases of no or low expression of somatostatin receptor, hypoglycemia may be exacerbated by inhibiting the secretion of competitive hormones, such as glucagon [1,3,38,39].

In malignant insulinoma, the mTOR inhibitor everolimus is effective for control of excessive insulin secretion and hypoglycemic symptoms [40,41].

Treatment of Resectable Insulinoma (Surgical Treatment)

Surgical resection is a radical treatment for insulinoma [1,3,5,42]. Surgical procedures differ depending upon the size and number of tumors, the tumor location, and whether MEN 1 is present or not [1–5]. Blind resection is not recommended for the occult insulinoma that cannot be preoperatively localized [2,43–45]. In general, enucleation is possible if the insulinoma is 2 cm or smaller and its distance from the main pancreatic duct is about 2–3 mm. In the case of damage to the main pancreatic duct, pancreatic partial excision, segmental resection, pancreaticoduodenectomy or distal pancreatectomy is carried out [43–45]. In patients with ineligibility for or refusal of surgery, several studies have demonstrated the safety and efficacy of endoscopic ultrasound-guided radiofrequency ablation [1,46].

Treatment of Unresectable Insulinoma

The therapeutic objectives in unresectable insulinoma cases are hormone symptom control and prolongation of prognosis [3,9,14,38]. Systemic chemotherapy for well-differentiated NEN (NET G1/G2) generally consists of a combination of streptozotocin and doxorubicin or fluorouracil. In recent years, dacarbazine- or temozolomide-based chemotherapy has also been used as the standard chemotherapy for insulinoma [14,38,47]. In 6–70% of well-differentiated NEN patients (insulinoma included), improvement of hormone symptoms or objective tumor response was demonstrated [38]. Among molecular target drugs, everolimus is considered effective against hormone oversecretion, and its antitumor effect has also been shown [40,41,48].

If medical therapy cannot sufficiently control hormone symptoms, tumor debulking surgery is sometimes conducted even in unresectable cases, targeting the removal of at least 90% of the tumor volume, with the objective of alleviating the symptoms [2,47,49].

Other therapies for unresectable NENs, including insulinoma, are liver-directed therapies (embolization, chemoembolization, radiofrequency ablation), laser-induced thermotherapy (LITT), selective internal radiotherapy (SIRT) using ^{90}Yttrium microspheres, peptide receptor radiotherapy (PRRT) with 177-Lutetium labeled somatostatin analogues, as well as liver transplant; alleviation of hormonal symptoms and improvement of prognosis have been reported [1,3,48–54].

Evidence of Medical and Surgical Treatment of Gastrinoma

Ryuichiro Doi

Graduate School of Medicine, Kyoto University, Kyoto, Japan
Otsu Red Cross Shiga Hospital, Shiga, Japan

Treatment Strategy

The goals of gastrinoma treatment are to manage gastric acid hypersecretion and to remove the risk of distant metastasis and ultimately death of the patient by resecting tumors that are usually malignant.

Treatment for gastrinoma has changed significantly since the syndrome was originally described in 1955 [1]. Initially, most patients developed severe symptoms and underwent emergency surgery for complications such as massive hemorrhage or perforation. Partial gastrectomy with or without vagotomy was insufficient so total gastrectomy became the standard operation for patients with gastrinoma [2].

The development of effective antisecretory drugs has drastically changed the management of gastrinoma [3]. In most patients, gastric acid hypersecretion can be controlled with antisecretory agents such as H_2-receptor antagonists and proton pump inhibitors. Because those agents are so effective, surgery for the control of gastric acid hypersecretion such as total gastrectomy is no longer required.

About 60% of gastrinomas are malignant and are the major cause of death during long-term follow-up, although they are relatively slow growing. Now, the roles of surgery are to remove the responsible tumor or tumors and prevent tumor progression and ultimately death.

Along with the increasing recognition of the duodenum as the most common site for gastrinomas, and with improved localization methods, at least 50% of patients with sporadic gastrinoma can be cured by tumor resection [1,4]. Therefore, an aggressive approach to tumor localization is strongly recommended in selecting patients for operative treatment.

Tumor Localization

Before surgical treatment, tumor localization studies are required in all patients with gastrinomas. Imaging techniques such as computed tomography (CT), ultrasonography (US), endoscopic ultrasonography (EUS), and intraoperative ultrasonography (IOU) have been useful for the localization of most neuroendocrine tumors greater than 2 cm in diameter [5]. However, imaging techniques have difficulty in visualizing neuroendocrine tumors smaller than 5 mm [5]. As gastrinoma shows characteristic symptoms even when smaller than 5 mm, the selective arterial secretagogue injection (SASI) test is useful for preoperative localization of gastrinoma leading to curative resection surgery [6–8]. Somatostatin receptor scintigraphy (SRS) and positron emission tomography (PET) with [68]Ga-DOTATOC are indispensable for localization of ectopic gastrinoma and the metastatic lesions of gastrinoma throughout the body [9,10].

Selective Arterial Secretagogue Injection Test with Secretin or Calcium

The SASl test was first described for localization of gastrinoma, and has gradually proved useful for the localization of other symptomatic pancreatic neuroendocrine tumors (panNETs) [6–8,11]. At the time of abdominal arteriography, secretagogue is injected into the splenic artery, gastroduodenal artery, and superior mesenteric artery (Fig. 113.1). Then 2 mL blood samples are drawn from the hepatic vein through a catheter inserted via the femoral vein before and at 20, 40, and 60 seconds after the injection of secretagogue to detect the change in gastrin levels in hepatic venous blood. When the rise in gastrin levels at

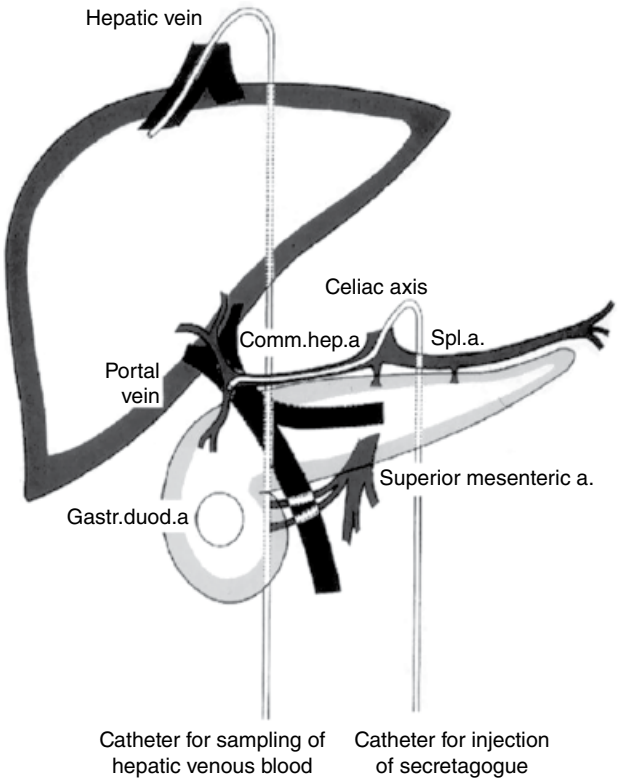

Figure 113.1 The selective arterial secretagogue injection test. Results of the selective arterial secretagogue injection (SASI) test in a patient with Zollinger–Ellison syndrome. In this patient, serum immunoreactive gastrin at 40 s after the injection of 30 units of secretin rose only after injection into the gastroduodenal artery. Hence it was diagnosed that the gastrioma(s) was located in the upper part of the pancreas and/or the duodenum. Gastr.duod.a, gastroduodenar artery; Spl.a., splenic artery; Superior mesenteric a., superior mesenteric artery.

40 seconds after injection is significantly higher than the measurement errors, the artery is diagnosed as a feeding artery of gastrinoma. Functioning gastrinoma is then located in the feeding area of the identified feeding artery.

More precise localization is possible by injecting secretagogue into a branch of the identified artery. Both the sensitivity and specificity of the SASI test for gastrinoma have been shown to be more than 90% [7].

In addition to secretin, which has been the first choice for injecting secretagogue for SASI, calcium gluconate solution is clinically used [12,13]. Unlike the response to secretin, the response to calcium gluconate is relatively slow; the SASI test by calcium gluconate is as useful as secretin in localizing gastrinoma if it is not detected by diagnostic imaging.

Somatostatin Receptor Scintigraphy

Somatostatin receptor scintigraphy can visualize PanNETs larger than 2 cm in diameter in the body, and has contributed to the staging of PanNETs [14–16]. SRS can visualize 100% of gastrinomas larger than 3 cm in diameter, but only 20% of gastrinomas are smaller than 5 mm and 30% are smaller than 1 cm [15]. SRS visualized 73% of gastrinomas, depending on the extent of the presence, the differences in subtypes of somatostatin receptors and the size of the tumor [16]. For the localization of ectopic gastrinoma, SRS is indispensable [17].

Intraoperative Ultrasonography

Intraoperative ultrasonography is useful in estimating the character of a tumor and in measuring the distance between gastrinoma and the main pancreatic duct. In addition, the form and size of the gastrinoma can be measured more accurately with IOU than any other preoperative imaging technique [18].

Surgery

Surgery for gastrinoma needs a thorough exploration and careful technique. The omentum is widely opened, and the entire pancreas from head to tail is mobilized. This allows careful bimanual palpation of the gland.

Intraoperative ultrasonography should be performed in any patient undergoing exploration for gastrinoma to identify tumors that are difficult to palpate. It may also detect signs suggestive of malignancy in addition to the relationship of the tumor to the main pancreatic duct and major blood vessels.

IOU is not particularly useful in identifying duodenal wall gastrinomas; however, intraoperative endoscopy with transillumination of the duodenum is capable of locating duodenal wall gastrinomas.

The most accurate method of detecting duodenal wall gastrinomas is duodenotomy with careful palpation, a technique employed by experienced surgeons during surgical exploration for gastrinoma. Duodenotomy has been shown to increase the gastrinoma detection rate to 98% compared with 76% without duodenotomy, and also the short-term cure rate (65% versus 44%) and long-term cure rate (52% versus 26%) [19].

Because primary duodenal gastrinomas are associated with lymph node metastases in 60% of patients, a more aggressive lymph node dissection has been recommended. Major vascular involvement is not a contraindication to attempting a resection. A study of 273 patients showed that 46 (17%) had evidence of major vascular involvement on preoperative imaging, and 42 of these 46 patients underwent successful resection [20].

The use of endoscopic and/or laparoscopic approaches for the management of neuroendocrine tumors, including gastrinomas, has been reported in small numbers of patients. However, the role for such an approach in patients with gastrinomas appears to be limited owing to a variety of technical issues, including the multiplicity of lesions, the small size of duodenal tumors, the frequent presence of lymph node metastases, and the presence of critical structures in the usual gastrinoma location in the pancreatic head region. These difficulties tend to favor an open surgical approach.

Treatment of Hepatic Metastases

A very aggressive management approach has been advocated for advanced and metastatic gastrinomas because of the poor outcome of patients and the overall disappointing results with systemic therapy. It was reported that aggressive resectional procedures were associated with no operative deaths and a five-year actuarial survival of 80% in 20 patients with locally advanced and metastatic neuroendocrine tumors, including 10 gastrinomas [21]. Another study in 85 patients with liver metastases suggested that chemoembolization may be preferred unless a curative resection is possible or 90% of the tumor volume can be removed [22]. Bilobar disease and patients with more than 75% liver involvement were least likely to benefit from surgery.

The role of liver transplantation in patients with liver metastasis remains controversial. The UNOS database showed that 150 liver transplantations were carried out for patients with liver metastasis from neuroendocrine tumors out of 87 280 performed. Among them, 11 cases of gastrinoma (7.3%) were included. Overall survival rates were similar to those for patients who underwent transplantation for hepatocellular carcinoma [23].

Other liver-directed therapies include chemoembolization, radioembolization, and percutaneous radiofrequency ablation. These therapies continue to play a role in the management of neuroendrocrine tumors metastatic to the liver, including gastrinomas. In general, transarterial chemoembolization (TACE) has been shown to be a relatively safe procedure with improvements in symptom control, time to progression, and survival.

Systemic Chemotherapy

Streptozocin appears to be the most active single agent in patients with metastatic gastrinoma, with objective response rates reported in up to 50% of patients [24]. There is no evidence that the addition of 5-fluorouracil (5FU) with or without doxorubicin improves the outcome compared with streptozocin alone [24].

A study using a combination of 5FU, cisplatin, and streptozocin for metastatic or locally advanced neuroendocrine tumors of a variety of sites in 79 patients showed that the overall results are not superior to those with streptozocin alone [25].

Octreotide, either alone or combined with interferon, appears to have a role in the management of patients. The development of a long-acting somatostatin analogue has greatly facilitated management, and it is effective in reducing symptoms.

A randomized multiinstitutional double-blind placebo-controlled trial studying the vascular endothelial growth factor (VEGF) inhibitor sunitinib was reported in 171 advanced well-differentiated neuroendocrine tumors, including 19 patients with gastrinoma. Progression-free survival (PFS) was 11.4 months in the sunitinib group compared with 5.5 months in the placebo group. The objective response rate was 9.3% in the sunitinib group versus 0% in the placebo group. Nine deaths were reported in the sunitinib group (10%) versus 21 in the placebo group (25%).

The use of mTOR inhibitors, either alone or combined with octreotide therapy, has recently been studied in patients with pancreatic neuroendocrine tumors. The RADIANT 1 trial, a multinational phase II study, studied the efficacy of everolimus alone and in combination with octreotide in patients with metastatic PanNET who had progressed on chemotherapy [26]. Treatment with everolimus alone resulted in stable disease in 67.8% of patients and partial response in 9.6%. Combination therapy with everolimus and octreotide LAR resulted in stable disease in 80% of patients and partial response in 4.4%.

In the RADIANT III trial, 410 patients with radiologic progression of disease were randomized to everolimus l0 mg daily or usual therapy, which could include somatostatin [27]. The median PPS was 11 months with everolimus compared with 4.6 months with usual therapy. The proportion of patients alive and progression free at 18 months was 34% with everolimus compared with 9% with placebo.

Rare Neuroendocrine Tumors of Pancreas: Management and Evidence of Surgical Treatment

Ryuichiro Doi

Graduate School of Medicine, Kyoto University, Kyoto, Japan
Otsu Red Cross Shiga Hospital, Shiga, Japan

Introduction

As pancreatic neuroendocrine tumors (PanNET) are rarely encountered in hospitals, standardization of diagnosis and/or treatment strategy has not progressed until recently. However, recent advances in localization techniques, such as the selective arterial secretagogue injection (SASI) test and somatostatin receptor scintigraphy (SRS), have promoted curative resection surgery of PanNETs [1,2]. As the number of resections has rapidly increased, a few important characteristic pathologic features of PanNETs have been revealed year by year.

PanNETs include both those associated with a functional syndrome (functional PanNET) and those associated with no distinct clinical syndrome (nonfunctional PanNET) [3–6]. Nonfunctional PanNETs are the most common but they do not usually produce specific symptoms and are therefore considered clinically to be nonfunctional tumors, but they produce and frequently even secrete small amounts of pancreatic polypeptide, chromogranin A, neuron-specific enolase, calcitonin, neurotensin, and other peptides [4,5,7–9]. Gastrinoma and insulinoma are the two most common functional PanNETs, but there are also various kinds of rare functional PanNET [3–6], including glucagonomas, vasoactive intestinal peptide-releasing tumors (VIPomas) (Verner–Morrison syndrome, pancreatic cholera, watery diarrhea, hypokalemia, and achlorhydria [WDHA] syndrome) and somatostatinomas (Table 114.1) [3-7,9]. Each of the established rare PanNET syndromes is associated with a distinct clinical syndrome reflecting the actions of the secreted excess hormone. Cholecystokinin (CCK)-releasing tumors (CCKoma) and secretin-releasing tumors (secretinoma) are further rare neuroendocrine neoplasms of which entities are being recognized [10,11].

Clinical Features

Gastrinoma, insulinoma, and nonfunctional PanNETs represent over 90% and other rare PanNETs less than 10% of all PanNETs [4,7]. Rare but well-known PanNETs include glucagonomas, VIPomas, and somatostatinomas whose syndromes are established. Rare and lesser known tumors include PanNETs that secrete CCK, secretin, calcitonin, renin, luteinizing hormone, erythropoietin, and insulin-like growth factor II whose status is unclear as to whether they represent a specific syndrome because of the small numbers of cases (see Table 114.1) [3–5,7,9–13].

The majority of patients with rare PanNETs have liver metastases at initial diagnosis (40–90%). Somatostatinomas can occur in the pancreas or upper small intestine; however, duodenal somatostatinomas are rarely associated with a functional clinical syndrome [4,12,14]. In addition to somatostatinomas, a number of other rare PanNETs also occur in extrapancreatic locations (see Table 114.1).

The average age at diagnosis is 50–55 years, with equal gender distribution. Patients with malignant tumors may present with mixed syndromes or tumors may change clinically over time. The most frequent familial condition associated with rare PanNETs is multiple endocrine neoplasia type 1 (MEN 1). Glucagonomas occur in 3% of MEN 1 patients, VIPomas in 3%, and GRHomas (secreting growth hormone-releasing hormone) and somatostatinomas in less than 1% [15,16]. Somatostatinomas are seen in up to

Table 114.1 Rare pancreatic neuroendocrine tumors (PanNET) Adapted from [3,5,7].

Name	Biologically active peptide(s) secreted	Estimated incidence (new cases/10^6 population/year)	Tumor location	Malignant (%)	Associated with MEN 1 (%)	Main symptoms/signs
Glucagonoma	Glucagon	0.01–0.1	Pancreas (100%)	50–80	1–20	Rash (67–90%); glucose intolerance (38–87%); weight loss (66–96%)
VIPoma	Vasoactive intestinal peptide (VIP)	0.05–0.2	Pancreas (90%, adult); other (10%, neural, adrenal, periganglionic)	40–70	6	Watery diarrhea (90–100%); hypokalemic (80–100%); dehydration (83%)
Somatostatinoma	Somatostatin	Rare	Pancreas (55%); duodenum/jejunum (44%)	>70	45	Diabetes mellitus (63–90%); cholelithiases (65–90%); diarrhea (35–90%)
CCKoma	Cholecystokinin	Rare	Pancreas	Unknown	Unknown	Nonwatery diarrhea; weight loss; gallbladder disease; duodenal ulcer disease; low plasma levels of gastrin
Secretinoma	Secretin	Rare	Pancreas	Unknown	Unknown	Watery diarrhea; dilated gallbladders; dilute bile; low plasma levels of VIP
GRHoma	Growth hormone-releasing hormone	unknown	Pancreas (30%); lung (54%); jejunum (7%); other (13%)	>60	16	Acromegaly (100%)
ACTHoma	ACTH	Rare	Pancreas (4–16% all ectopic Cushing)	>95	rare	Cushing syndrome (100%)
PanNET causing carcinoidsyndrome	(Serotonin; tachykinin)	Rare	Pancreas (<1% all carcinoids)	60–88	rare	Carcinoid syndrome
PanNET causing hypercalcemia (PTHrp-oma)	PTHrp; others unknown	Rare	Pancreas (rare cause of hypercalcemia)	84	rare	Abdominal pain due to hepatic metastases, symptoms due tohypercalcemia
PanNET secreting calcitonin	Calcitonin	Rare	Pancreas (rare cause of hypercalcitonemia)	>80	16	Diarrhea (50%)
PanNET secreting renin	Renin	Rare	Pancreas	Unknown	no	Hypertension
PanNET secreting luteinizing hormone	Luteinizing hormone	Rare	Pancreas	Unknown	no	Anovulation, virilization(female), reduced libido (male)
PanNET secreting erythropoietin	Erythropoietin	Rare	Pancreas	100	no	Polycythemia
PanNET secreting insulin-like growth factor II	Insulin-like growth factor II	Rare	Pancreas	Unknown	no	Hypoglycemia

ACTH, adrenocorticotrophic hormone; MEN, multiple endocrine neoplasia.

l0% of patients with von Recklinghausen disease (neurofibromatosis type 1) but in almost all cases they are not associated with a functional syndrome [7,14,15].

Prognosis and Survival

Most rare PanNETs present with metastatic disease and patient survival time is determined by growth of the tumor rather than the hormone excess state. Five-year survival for the group with advanced disease is 29–45% [3,4,6,7]. All the survival or prognostic data on the individual rare PanNETs come from retrospective studies and their results are often included in noninsulinoma or nongastrinoma series that include nonfunctional PanNETs. These studies demonstrated tumor Ki-67 index ≥62%, presence of lymph node metastasis, presence of cytokeratin-19 staining, and various molecular features that were associated with a poor prognosis [4,17].

Diagnosis

Rare PanNETs characteristically present with symptoms of the specific hormone excess state, and in most cases present late in the disease course when advanced disease is already present [4,6,7]. In a few patients with a rare PanNET, a second functional syndrome may develop over time. Therefore, the diagnosis of all rare PanNETs requires demonstration of an inappropriate elevation of the specific serum hormones combined with clinical and/or laboratory evidence of oversecretion of the appropriate hormone [3–5,18,19]. The diagnosis of functional rare PanNET requires clinical evidence of hormonal overexpression and is not based solely on immunohistochemical results [3–5,18,19].

General markers such as serum chromogranin A also support the presence of a neuroendocrine tumor, and may be helpful for monitoring during the disease's course [3,5,19,20].

All biochemical tests should be performed at first visit. PanNETs causing Cushing syndrome should be suspected from the clinical examination and history, and the diagnosis established by performing 24-hour urinary cortisol determinations, midnight plasma or salivary cortisol assessments, and dexamethasone suppression tests as needed [9,19].

Theoretically, pancreatic cells that produce any kind of hormones can become neoplasms. As we do not have methods of measuring serum concentration of the candidate responsible hormone, that is, a specific antibody, we cannot diagnose that the tumor is the hormone-producing neoplasm which causes the unique symptoms. In this sense, the existence of CCKoma has been suspected and a case was reported with extremely elevated plasma cholecystokinin level and permanently low plasma gastrin level [10]. The CCKoma symptoms include persistent nonwatery diarrhea and weight loss combined with more specific symptoms of gallbladder disease and duodenal ulcer disease.

Similarly, Zollinger et al. postulated the existence of secretin-releasing tumor five decades ago based on the characteristic clinical symptoms such as watery diarrhea, hypokalemia and achlorhydria without hypergastrinemia [21]. Recently, thorough laboratory work has been done on the same specimen from half a century ago, leading to the conclusion that the tumor was almost certainly a secretinoma [11]. However, as there was no measurement of plasma secretin, which is the *sine qua non* to establish a hormone as potentially causing a clinical syndrome, the diagnosis must be tentative.

Tumor Localization

Tumor localization studies are important in all patients with rare PanNETs. They are necessary to determine whether surgical resection is indicated, to localize the primary tumor, to determine the extent of the disease and whether metastatic disease to the liver or distant sites is present, and to assess changes in tumor extent with treatments. All aspects of their management require knowledge of tumor extent. It is important to know that the majority of all pancreatic functional tumors except insulinomas are malignant. Accurate localization of the tumor can result in complete surgical resection with cure of PanNET (10–40%).

Numerous localization studies have been recommended, including conventional imaging studies (computed tomography [CT], magnetic resonance imaging [MRI], ultrasonography [US]), selective angiography, SASI test, SRS, and endoscopic ultrasonography (EUS), in addition to various intraoperative localization methods including intraoperative ultrasonography (IOU).

Most prospective studies show that the sensitivity of conventional imaging studies for localizing the primary tumor is 10–50%, angiography 20–50%, and SRS 30–70% [22]. The use of SRS changes management in 15–45% of patients with PanNETs. For SRS and all conventional studies, tumor size is an important variable and tumors smaller than 1 cm are missed in 50% or more cases. The combined use of multidetector CT (MDCT) scanning or MRI and SRS is always recommended. Conventional imaging studies suggesting vascular or tissue invasion may provide important information on whether surgical resection is contraindicated.

If measurement of target hormone is easily accessible, the SASI test is the most reliable approach for tumor localization. This test was first described for localization of gastrinoma, and has gradually proved useful for localization of other functional PanNETs [2,23–25]. At the time of abdominal arteriography, secretagogue is injected into the splenic artery, the gastroduodenal artery, and superior mesenteric artery. Then 2 mL blood samples are drawn from the hepatic vein through a catheter inserted via the femoral vein, before and 20, 40, and 60 seconds after the injection of secretagogue to detect the change in hormone levels in hepatic venous blood. When the rise in hormone levels at 40 seconds after injection is significantly higher than the measurement errors, the artery is diagnosed as a feeding artery of the tumor. Functioning tumor is then located in the feeding area of the identified feeding artery.

Functional localization studies are not limited by tumor size but are somewhat invasive. Prospective studies of the metastatic liver disease from a malignant PanNET showed that CT and US could detect their presence in 30–80% of patients with metastases, MRI and angiography in 50–85%, and SRS in 70–95% [26]. IOU should be routinely used to assess and identify PanNETs [27].

Endoscopic US is particularly sensitive for PanNETs but its ability to detect small duodenal tumors is controversial. Hence, EUS is not universally recommended as a first-line procedure in the investigation of rare PanNETs. It may be used in circumstances where MDCT, MRI, and SRS are inconclusive, especially preoperatively. However, in patients with rare PanNETs presenting with lymph node metastasis, EUS is rarely necessary. It may be helpful in patients with large or aggressive tumors to more clearly define tumor involvement where surgery is considered.

Insufficient data are available to recommend positron emission tomography (PET)/CT methods on a routine basis; their use remains investigational and availability is limited. If results with the earlier recommended imaging methods are unclear or negative in a patient with rare PanNET, ^{68}Ga-labeled somatostatin analogue PET should be considered with performance by an experienced center.

A number of studies have demonstrated that PET, especially with ^{68}Ga-labeled somatostatin analogues (DOTA-TOC [DOTA-Tyr-octreotide], DOTA-TATE [DOTA-Tyr-octreotate], DOTA-NOC [DOTA-naloctreotide]) when combined with CT ([^{68}Ga] DOTATOC PET/CT, for example), has high specificity and is more sensitive than SRS or other modalities [28–31]. At present, it is not available in many centers and its exact place in the localization algorithm has not been clearly defined.

Standard PET with [^{18}F]fluoro-2-deoxy-D-glucose (FDG-PET) is not efficient in detecting well-differentiated tumors but may have some value in the detection of aggressive, poorly differentiated pancreatic neuroendocrine carcinomas [7]. Other examinations that may be useful are [^{18}F]DOPA-PET or [^{11}C]-5-HTP-PET if available and costs are affordable.

Surgical Treatment

The best treatment for rare PanNET is curative surgical resection. This needs to be performed before liver metastasis develops. Indications for surgery depend on clinical symptom control, tumor size, location, extent, malignancy, and metastatic spread [3,4,7,27,32].

Curative surgery should be indicated whenever possible, even in the presence of metastatic disease, including resectable metastatic disease to the liver and when the patient can tolerate the surgery [3,4,7,27,32]. The types of surgery include pancreaticoduodenectomy, distal pancreatectomy, tumor enucleation, and enucleation in combination with resection, depending on the location of the primary tumor.

Curative surgery is always recommended following optimal symptomatic control of the clinical syndrome by medical treatment. Owing to the usually large size of the tumor and the high prevalence of lymph node metastasis in rare PanNETs, curative surgery should include pancreatic resection with lymph node dissection through laparotomy. In the case of localized lymph node metastasis or more extensive disease spread, surgery should also be considered if at least 90% of the gross tumor can be resectable.

Laparoscopic resection is currently not recommended because lymphadenectomy and careful inspection for invasion and metastases are needed [7]. Surgery for lymph node metastasis may be performed during treatment of the primary tumor. Cytoreductive surgery should be considered when the metastatic disease is localized or more than 90% of the tumor load can be resected, which may help to improve hormonal control and perhaps extend survival.

Another indication for surgery is an emergency of life-threatening severe symptoms. Emergency pancreatic resection is sometimes necessary for glucagonoma associated with paraneoplastic syndromes such as severe necrolytic migratory erythema or VIPoma with profuse watery diarrhea or renal failure. When the symptoms are caused by the primary pancreatic tumor, pancreatectomy is necessary although the surgery is invasive to patients [33]. On the other hand, if the symptoms are caused by metastatic tumors of the liver, transarterial chemoembolization (TACE) may be chosen first, then elective surgery should be planned [34].

Medical Treatment

Several decades ago, the major cause of death of patients was the untreated effects of the hormone excess state; therefore, it is important to control the hormone levels [4,7], which can be achieved with the combined use of medical, surgical, and radiologic therapies.

Both somatostatin analogues and interferon have been shown to be effective in the control of symptoms in rare PanNETs [35]. Somatostatin analogues provide effective symptom control in patients with VIPomas, GRHomas, and glucagonomas [35]. Long-acting somatostatin analogues are also reported to be effective in controlling the excess hormone secretion in some cases of somatostatinomas. If somatostatin analogues are ineffective or lose efficacy in controlling the hormone excess state, interferon may be effective at controlling the symptoms, either alone or in combination with somatostatin analogues.

Somatostatin analogues also have antigrowth effects on PanNETs. For the control of symptoms, somatostatin analogue therapy should be initiated with the short-acting substance for 1–2 days with titration according to clinical response. The patient can then be transferred to slow-release lanreotide-SR IM, lanreotide Autogel-SC, or octreotide long-acting release IM every four weeks [36]. Likewise, interferon treatment may help control symptoms of the hormone excess state in rare PanNETs, although it has been less well studied than the use of somatostatin analogues. It is reported to be effective in VIPomas not responding to somatostatin analogues and also in isolated cases when combined with somatostatin to control the symptoms of a rare PanNET, which with somatostatin treatment alone was inadequately controlled; however, this requires confirmation in future studies [37].

Prospective studies of mammalian target of rapamycin (mTOR) inhibitors with or without octreotide and tyrosine kinase inhibitors have shown significant prolongation of survival time in patients with gastrinoma. New cytotoxic chemotherapy with temozolomide and capecitabine has also been reported to be effective.

Introduction

Neuroendocrine neoplasia (NEN) of the pancreas, duodenum, and biliary tract constitute a rare and heterogeneous group of neoplasms. Historically, the term "carcinoids" has been used to define these tumors. Modern pathology classification based on grading utilizing the Ki-67 index, or number of mitoses per 10 high-powered fields (HPF), has introduced the term "neuroendocrine neoplasia." Neuroendocrine neoplasms may be classified as neuroendocrine tumors (NET) or neuroendocrine carcinoma (NEC). Grade 1 (NET) have a Ki-67 of <3% or <2 mitoses per 10 HPF. Grade 2 (NET) have a Ki-67 of between 3% and 20%, or between 2 and 20 mitoses per 10 HPF. Grade 3 NEN have a Ki-67 of >20%, or >20 mitoses per 10 HPF, and can be subclassified into G3 NET and G3 NEC; this is on the basis of their differentiation: G3 NET are well differentiated and G3 NEC are poorly differentiated [1].

A hallmark of NEN is the secretion of amines and peptides capable of inducing distinct clinical syndromes. Beside tumor-specific hormones including insulin or gastrin, proteins such as neuron-specific enolase (NSE), chromogranin A (CgA), pancreastatin, and synaptophysin—commonly expressed in neuroendocrine cells—are produced. Such proteins serve for immunohistochemical NEN diagnosis, and have been recognized as clinically useful tumor markers. Some pancreatic NEN (PanNEN) secrete multiple hormones and may show secondary changes in the secreted hormone profiles during their clinical course. Additional characteristic features of NEN encompass specific amine uptake mechanisms and cell surface peptide receptors, i.e., for somatostatin, that have utility in diagnosis and treatment [2].

Recently, circulating multianalyte biomarkers have been introduced in the management of NEN which allow disease detection and prediction of treatment effectiveness and prognosis [3]. Other novel biomarkers such as circulating tumor cells, cell free DNA, circulating tumor DNA, mRNA, and microRNA still require validation in clinical practice.

Neuroendocrine neoplasia can occur sporadically or as a component of the genetically determined autosomal dominant syndromes including von Hippel–Lindau, multiple endocrine neoplasia type 1 (MEN 1), neurofibromatosis type 1, and tubular sclerosis. In cases of heredity, multicentric tumor manifestation should be expected.

Neuroendocrine Neoplasia of the Pancreas

Of the NEN originating from the pancreas, 65–80% are hormonally active. Whilst the majority secrete insulin or gastrin, less commonly, secretion of vasoactive intestinal polypeptide (VIP), glucagon, growth hormone-releasing factor (GRF), or somatostatin is observed. Particularly rare are serotonin-producing tumors. Tumor nomenclature depends upon the hormone predominantly secreted, namely insulinoma, gastrinoma, VIPoma, glucagonoma, GRFoma or somatostatinoma.

There has been significant progress in the understanding of genomic events that characterize PanNEN; such mutations and other molecular alterations have a role in pathogenesis of these tumors but also determine their prognosis [4]. Surgery plays a central role in management of PanNEN and is considered as a first-line treatment option for patients with resectable disease. Under consideration of favorable long-term survival of

many surgical patients with G1 or G2 PanNEN, long-term pancreatic functional impairment in terms of diabetes mellitus and/or pancreatic exocrine insufficiency has to be taken into account, particularly when planning extensive pancreatic resections in those with preexisting morbidity [5]. Several areas are subject to ongoing debate, such as extent of resection in MEN 1-associated gastrinoma, primary tumor resection in the presence of nonresectable liver metastases, managment of patients with incidentally discovered small nonfunctional Pan NEN, clinical significance of lymph node metastases in PanNEN, and the role for neoadjuvant treatment for borderline resectable tumors [6].

Insulinomas

Insulinomas represent 60% of functional PanNEN. More than 90% of such tumors are benign lesions measuring 1–2 cm in size (Fig. 115.1). Approximately 10% of insulinomas are multicentric, and most of them are associated with MEN 1. Malignant insulinomas metastasize to the regional lymph nodes and liver. Localized or diffuse islet cell hyperplasia is a very rare cause of hyperinsulinemic hypoglycemia, and has been reported in adults and children (nesidioblastosis). The clinical hallmark of the disease is neuroglycopenia, followed rather regularly by catecholaminergic responses.

The diagnosis of insulinoma is based on following criteria:

- the signs and symptoms of hypoglycemia during periods of fasting or exertion
- documented blood glucose levels near or below 40 mg/dL (<2.2 mmol/L)
- concomitant insulin levels of ≥6 μU/mL (43 pmol/L)
- elevated C-peptide levels (≥0.2 nmol/L)
- absence of sulfonylurea in the plasma.

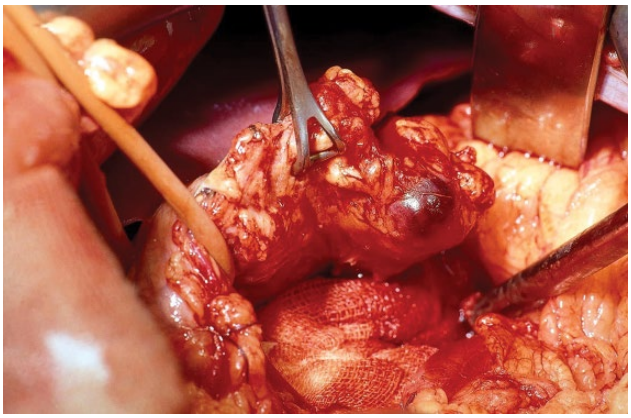

Figure 115.1 Intraoperative finding of a 1 cm insulinoma at the tail of the pancreas.

As the most reliable investigative test, 72-h fast has been traditionally considered. In the presence of insulinoma, 80% of patients will become symptomatic within 24 hours of fasting. With the introduction of upgraded assays for insulin, proinsulin, and C-peptide, the standard full 72-h fast might be replaced by the 48-h fast [7]. Although rarely required, provocative tests (tolbutamide test, glucagon test, calcium infusion test) can be of help in cases of anomalous or equivocal results. After establishing a biochemical diagnosis of insulinoma, a search for adenopathies typical for MEN 1 and meticulous evaluation of the family history must be carried out. The diagnosis of MEN 1-associated insulinoma can be confirmed by DNA analysis and by proof of menin gene mutations most commonly detected in exons 2, 7, 9, and 1.

Localization Studies

The striking advantage of preoperative localization of PanNEN has been recognized. In the presence of newer imaging techniques and refinement of standard radiologic procedures, the vast majority of lesions can be accurately identified prior to surgery.

A high-quality arterial and portal venous phase computed tomography (CT) according to a pancreatic protocol is the gold standard imaging modality for primary tumor staging and direction of therapy. Apart from tumor localization within the pancreas, it ascertains the vascular anatomy of the pancreas, identifies biliary and pancreatic duct abnormalities, and assesses for invasion of peripancreatic structures and nodal metastases. Features suggestive of a PanNEN on CT include the presence of a hypervascular or hyperdense lesion within the pancreas; however, they can also appear cystic or contain calcifications. Most insulinomas are <2 cm in size and solitary. On CT, they tend to be hypervascular with either uniform or target enhancement; however, given that they are often noncontour-conforming, detection of the vascular blush is essential to localize them (the chance of detection can be maximized by timing the images 25 seconds after contrast injection). Magnetic resonance imging (MRI) features include low signal intensity on T1-weighted images and the lesions are particularly well seen on fat-suppressed (T1- and T2-weighted) images [8].

The sensitivity of transabdominal ultrasound strongly depends on the experience of the examiner and has been reported to be around 60–70%. The use of contrast with microbubbles (CEUS) improves the sensitivity of US due to hypervascularity of most NEN. For endoscopic ultrasound (EUS) imaging of PanNEN, overall sensitivity and accuracy of up to 95% have been reported but this is operator dependent [9]. Either as a single technique or in combination with fine needle aspiration biopsy, which can confirm the diagnosis and inform tumor grade, it has

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. emerged as one of the most valuable modalities in the imaging of PanNEN.

Previously widely used ^{111}In-pentetreotide scintigraphy (Octreoscan®) was not very effective in the radiologic interrogation of insulinomas since most of the lesions do not express somatostatin receptor subtype 2, necessary for binding of the radiolabeled octreotide. Glucagon-like peptide-1 receptor imaging (^{111}In-DTPA-exendin-4 SPECT/CT) has recently been reported as an effective second-line imaging modality for patients with negative results on standard imaging [10].

Intraoperative ultrasonography enables identification of the lesion, and provides additional information concerning the relation of the tumor to the pancreatic duct, common bile duct, portal vein, and superior mesenteric vessels. Particularly for tumors located within the uncinate process, exposure of the complete gland is crucial.

Assignment of insulinomas to regions of pancreas is possible by selective transhepatic portal venous sampling for insulin. The method regionalizes the lesion to a certain part of the pancreas but it does not determine the specific location. Since this highly invasive technique is extremely demanding, it is reserved mainly for reoperations and MEN 1-associated tumors [11]. Further improvement of tumor regionalization can be achieved by selective arterial calcium stimulation and blood sampling for insulin gradients in the hepatic veins, a technique originally reported by Imamura and Takahashi for regionalization of gastrinomas [12].

Perioperative Management of Serum Glucose

The main goal of the preoperative preparation is to avoid severe hypoglycemia. Intravenous administration of glucose is recommended the night before surgery. Severely hypoglycemic patients may be treated with diazoxide or octreotide. Intraoperatively, blood glucose monitoring should continue. Increases in blood sugar levels may confirm successful insulinoma removal. More reliable confirmation concerning completeness of surgery can be gained by insulin measurement with intraoperative rapid insulin assay. Shortly after insulinoma removal, transient hyperglycemia usually occurs. Since glucose levels rarely exceed 200 mg/dL, no specific treatment is necessary.

Surgical Management

In patients with tumors expressing malignant features, or in the presence of contradicting imaging results, a standard surgical approach to the pancreas and exploration of the liver for metastases includes meticulous exposure of the whole organ including the uncinate process, allowing visual assessment of anterior and posterior pancreatic surfaces. Even if the lesion is already visible, intraoperative US should be performed to assess the relationship of the tumor to the surrounding structures. Regardless of the specific site of the tumor, enucleation or limited parenchyma-sparing resection should be attempted as the "gold standard" for surgical treatment of benign insulinoma. When selecting patients for enucleation, the distance of the tumour of more than 2–3 mm from the main pancreatic duct should be considered as one of the inclusion criteria.

Blunt dissection close to the capsule of the tumor with the aim of avoiding injury to the main pancreatic duct is recommended in order to prevent fistula formation. The parenchymal defect can be closed or left open. Local application of sealants can lower the incidence of postoperative fistulae, traditionally reported with an incidence of 13–40%, irrespective of the management of the enucleation cavity [13]. Perioperative octreotide administration has not been shown to reduce the risk of postoperative pancreatic fistulae.

Laparoscopic resection of PanNEN is feasible and safe, particularly in left-sided lesions [14]. The value of robotic surgery in treatment of PanNEN is currently under investigation [15]. The majority of patients with sporadic insulinomas localized on imaging and selected patients with MEN 1-associated insulinomas nowadays undergo laparoscopic resections. The rate of fistulae, however, remains comparable to that in open surgery. If the tumor is not identifiable, blind resections cannot be recommended. Rather than performing a blind distal pancreatectomy, the procedure should be stopped and the patient referred to a center with the possibility of advanced localization techniques and adequate surgical experience [16].

Larger lesions within the body or tail are managed by distal pancreatectomy with preservation of the spleen, if technically feasible. Very rarely seen large tumors within the head of the pancreas, or tumors located deeply within the parenchyma and in close proximity to the pancreatic duct, require partial cephalectomy or even pancreaticoduodenectomy. For tumors located within the middle portion of the gland that cannot be enucleated due to proximity to the main pancreatic duct, central segmental pancreas resection may be the appropriate technique.

Insulinomas associated with the MEN 1 syndrome are invariably multifocal and scattered throughout the whole pancreas. Although the number of well-documented patients is rather small, distal subtotal pancreatectomy with splenic preservation and enucleation of any tumors in the head and/or uncinate process appears to be the best procedure. Peripancreatic lymphadenectomy is recommended in patients with concomitant gastrinoma or suspected malignancy [17].

Gastrinoma

Zollinger–Ellison syndrome (ZES) is the clinical manifestation of gastrinomas. Whilst virtually all gastrinomas derive from the duodenum, some patients present with additional pancreatic lesions. In 60–90% of cases, gastrinomas can be found within the "gastrinoma triangle" defined by the junction of the cystic and common bile duct posteriorly, the junction of the second and third portion of the duodenum inferiorly, and the junction of the pancreatic neck and body medially. Although subject to controversial debate, the existence of primary lymph node gastrinomas has been postulated [18]. The majority of the duodenal gastrinomas are multicentric and only a few millimeters in size. Approximately 40% are linked to the MEN 1 syndrome [19]. In contrast to insulinomas, sporadic gastrinomas are frequently malignant and greater than 2 cm in diameter. Depending upon primary tumor size, liver metastases in combination with paraduodenal and peripancreatic lymph node metastases can be found at initial diagnosis in up to 70% of patients [20].

Localization Studies

Sensitivity of standard imaging techniques (US, CT, MRI) has been reported to be between 40% and 70% for pancreatic gastrinomas sized 1–3 cm [21]. Endoscopic ultrasonography provides 75–90% sensitivity for pancreatic gastrinomas and 50–70% sensitivity for duodenal wall lesions [22]. For the majority of localized gastrinomas and for metastatic disease, SR-based imaging utilizing PET/CT technology (e.g., gallium-68 [^{68}Ga]1,4,7,10-tetra-azacyclododedcan-4,7,10-tricarboxy-methyl-1-yl-acetyl-D-Phe^{1} Try^{3}–octreotide [^{68} Ga-DOTATOC], ^{68} Ga-DOTATOC PET/CT) is the single most accurate localization method [23]. In order to preoperatively localize gastrinomas which remained undetectable by standard imaging techniques, Imamura et al. developed the selective arterial secretagogue injection (SASI) test with secretin or calcium, which can guide surgical management [12].

Surgical Management

Surgical exploration with an attempt at tumor resection is recommended for all sporadic gastrinomas in the absence of multiple nonresectable liver metastases [24]. Compared with medical treatment, surgical tumor removal significantly reduces the risk of metachronous liver metastases [25]. If the test result indicates a tumor within the duodenum only, 80% of patients with sporadic gastrinomas might be successfully treated with resection of the single tumor and periduodenal lymphadenectomy [26]. The remaining 20% typically have multiple duodenal gastrinomas, or a combination of duodenal and pancreatic tumors. In patients presumed to have a sporadic gastrinoma in whom no preoperative SASI test was carried out, pancreatic and duodenal exploration is necessary. Intraoperative US, careful palpation, and endoscopic transillumination of the duodenal wall are extremely valuable aids. For larger gastrinomas in the head of the pancreas without duodenal tumor, pylorus-preserving pancreatoduodenectomy is recommended. Small tumors (<5 mm) can be enucleated from the submucosa while larger tumors require full-thickness excision. In the case of duodenal and pancreatic lesions, pancreatoduodenectomy presents the appropriate therapy. Distal pancreatectomy with regional lymphadenectomy is the treatment of choice for gastrinomas within the body or tail of the pancreas [27].

For MEN 1-associated gastrinomas, recommendations for surgery are much more controversial concerning timing and extent of the procedure [28]. While some authors are in favor of less aggressive surgery encompassing spleen-saving distal pancreatectomy, enucleation of NEN within the head and uncinate process, duodenotomy and excision of NEN, and regional lymph node dissection, others propose more aggressive duodenopancreatic resections in order to achieve durable eugastrinemia [29].

Liver metastases are the main prognostic determinant in patients with gastrinomas. No uniform guidelines for management of tumors in advanced metastatic stage exist. Treatment options are the same as those for other NET metastasized to the liver or primary NET of the liver (see below).

Nonfunctioning Tumors

Patients with nonfunctioning (NF) (nonsecreting) pancreatic NETs have no clinical symptoms related to hormonal hyperfunction, and negative biochemistry for peptides secreted by the pancreatic islets. Immunohistochemically, however, expression of hormones in tumor cells can be revealed. The reported incidence of NF pancreatic NEN varies between 15% and 53% [30] and the majority of such tumors are malignant. Lesions can occur sporadically or within the MEN 1 syndrome. At time of diagnosis, most symptomatic patients are between 40 and 60 years old, presenting with abdominal pain, jaundice, and weight loss. Tumors located within the body or tail of the pancreas may be clinically silent yet palpable as a bulky mass. In the past, the majority of tumors were diagnosed at an advanced stage. Nowadays, however, small NF NEN are increasingly diagnosed incidentally on imaging for reasons unrelated to the pancreas.

Upon diagnosis, differentiation from pancreatic adenocarcinoma must be considered. In general, patients with NF NEN are in a better clinical condition. Synchronous metastases in the liver and/or lymph nodes

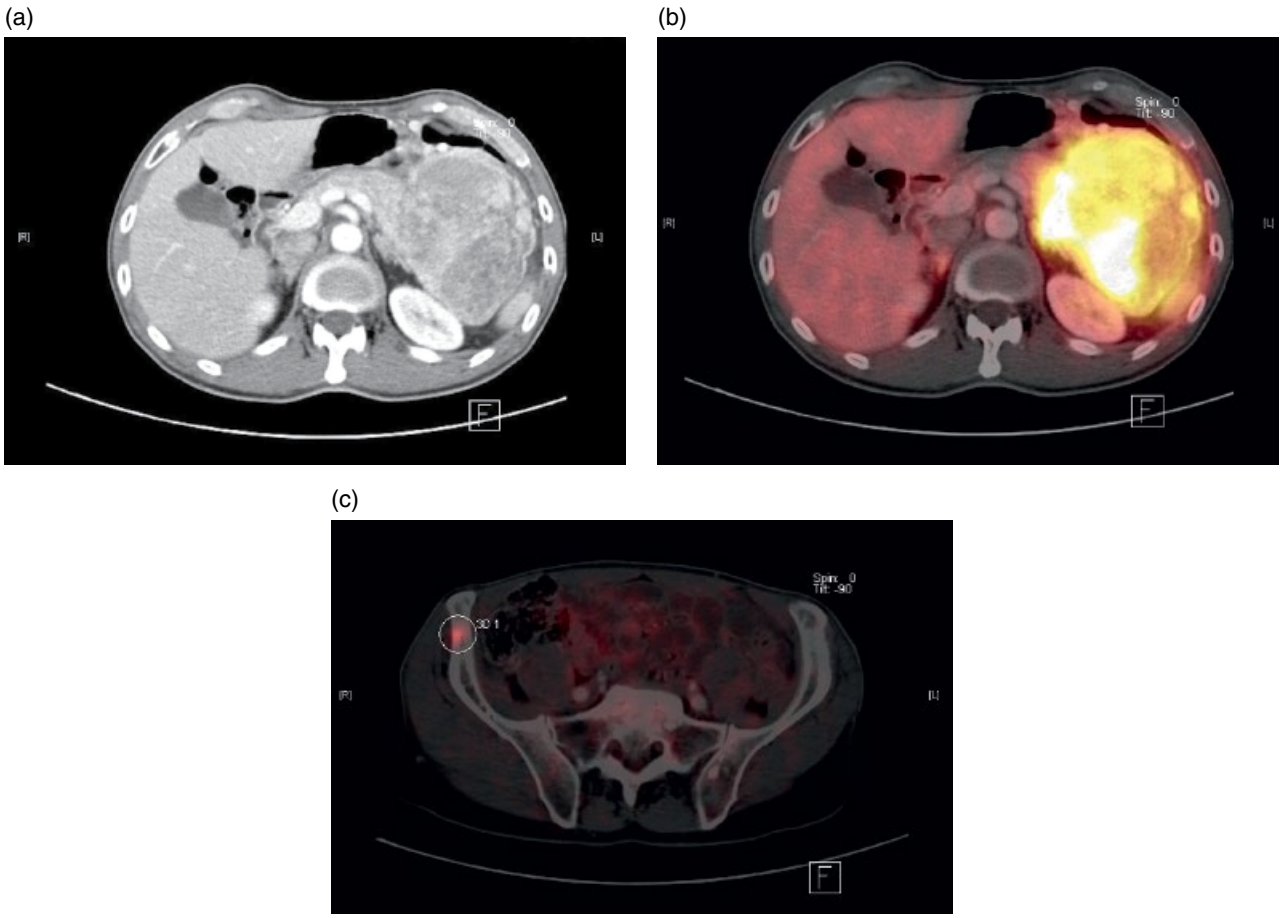

Figure 115.2 Preoperative imaging studies in a patient with a nonfunctioning NENof the pancreas. (a) On CT scan, a 20 cm diameter tumor in the left abdomen is shown. (b) ^{68}Ga-DOTATOC PET/CT demonstrates significant radionuclide uptake in the left upper abdomen. (c) Additionally, pathologic uptake, indicating a metastasis, is demonstrable within the right ilium (c). This finding was not seen on CT scan.

are frequently present. In our experience, ^{68} Ga-DOTATOC PET/CT is the most valuable imaging technique for staging well-differentiated and moderately differentiated NF NEN (Figure 115.2). For higher grade tumors or poorly differentiated neuroendocrine carcinomas, ^{18}F-fluorodeoxyglucose PET/CT (^{18}F-FDG PET/CT) is a more accurate imaging modality.

Resection is the treatment of choice for sporadic nonfunctioning G1/G2 and selected G3 PanNEN [30]. Resection rates of 26–79% with an overall five-year survival of 30–80% are reported [31]. In locally advanced tumors, multivisceral resections might be required to achieve an R0 situation. Because of the protracted natural history of these tumors, and given that many are symptomatic and difficult to palliate without resection (e.g., tumor bleeding), the criteria for what determines unresectable disease may not be the same as those for adenocarcinoma of the pancreas. The MD Anderson experience suggests that, in high-volume centers, major venous reconstruction can be performed safely, but only rarely should arterial reconstruction (isolated hepatic artery involvement) or upper abdominal exenteration be performed, due to the associated high long-term morbidity [32]. Continuous somatostatin analogue infusions are recommended perioperatively for carcinoid tumors and/or patients with liver metastases to prevent intraoperative carcinoid crisis.

For MEN 1-associated NF NET of the pancreas, no uniform suggestions exist. While some authors suggest resection of all tumors regardless of size as soon as visualized, others postulate that considering risk–benefit ratios, surgery may not be necessary in tumors less than 2 cm in diameter [33]. Controversy also exists regarding management of sporadic small (<2 cm) NF NEN; while in the opinion of some groups these tumors can be treated conservatively, others recommend surgical resection since both liver metastases and lymph node metastases have been reported in single patients with NF NEN less than 2 cm in size [34]. Currently, patients should be assessed regarding fitness for surgery and an

informed decision made with the patient regarding strategy under consideration of operative morbidity and mortality risks. Central pancreatectomy may be feasible for selected smaller tumors and has the advantage of reducing the risks of postoperative diabetes and exocrine pancreatic insufficiency. A formal resection with lymphadenectomy should be performed for all potentially malignant tumors as lymph node metastases are common.

Another topic of ongoing debate is the resection of primary NF pancreatic NEN in the setting of unresectable liver metastases. Although evidence quality of the existing reports in favor of primary tumor resection is rather poor, the resectional aproach can be justified in selected patients with tumors amendable for distal pancreatectomy and synchronous liver metastases suitable for interventional or medical treatment [35]. Recently, peptide receptor radionuclide therapy has been introduced in the multimodal management of advanced pancreatic NET as a potential tool for downstaging in patients with primarly nonresectable tumors [36].

Neuroendocrine Tumors of the Duodenum

Duodenal NEN accounts for 2.5–3% of all tumors originating from the gastrointestinal tract [37]. Their management is not standardized, with smaller tumors considered for endoscopic mucosal resection and larger for surgical resection. The location within the duodenum is of prognostic relevance and plays a role in the decision regarding extent of surgery [38]. Histopathologically, five types of duodenal NEN can be discriminated, namely duodenal gastrinomas, somatostatinomas, nonfunctioning serotonin-, gastrin, or calcitonin-producing tumors, poorly differentiated and predominantly ampullary NE carcinomas, and duodenal gangliocytic paragangliomas. Approximately 30% of duodenal NEN are related to von Recklinghausen disease (neurofibromatosis type 1 [NF1]), MEN 1, and/or pheochromocytomas. The majority of duodenal NEN express CgA and NSE.

Gastrinomas located in the first and second portion of the duodenum account for approximately two-thirds of all duodenal NEN. These tumors occur either sporadically or as a component of the MEN 1 syndrome. Sporadic as well as hereditary tumors are generally small (<1 cm), but are multifocal in cases of familial determination. Although of small size and growth limited to the mucosa and submucosa, duodenal gastrinomas frequently present with lymph node metastases [39]. In contrast to pancreatic gastrinomas, distant metastases rarely occur in sporadic and hereditary duodenal tumors [28].

Duodenal somatostatinoma, located either within the ampulla of Vater or periampullary, account for 15% of all duodenal NEN. Insular growth pattern and psammoma body formation are the histologic hallmarks of these tumors. With muscularis propria infiltration, malignancy must be assumed. Tumor size and mitotic activity have no correlation with metastatic potential [40]. Somatostatinoma syndrome, typical for pancreatic NEN expressing somatostatin, does not occur in these duodenal tumors. Due to the unpredictable behavior of ampullary or periampullary NEN, a radical surgical approach, most frequently in form of a Whipple procedure, is recommended [40].

Nonfunctioning duodenal NEN has complex prognoses. While well-differentiated tumors confined to submucosa behave benignly, advanced metastases are frequently associated with poorly differentiated neoplasms. Gangliocytic paragangliomas represent a unique subgroup of duodenal NEN located within the periampullary region, and despite a tumor size >2 cm and infiltration of the muscularis propria, they generally have benign clinical course.

With the exception of ampullary/periampullary NEN, duodenal NEN smaller than 1 cm, and in the absence of signs of invasion of the muscularis propria and of metastases, may be excised locally by endoscopic resection with or without submucosal saline injection [41]. In this regard, endoscopic ultrasonography proved to be of extremely high value. It should be stressed, however, that lymph node metastases can be found in tumors less than 1 cm size [42]. For tumors between 1 and 2 cm or larger, local full-thickness excision through an open transduodenal approach or segmental duodenal resection with a side-to-side duodenostomy and regional lympadenectomy are recommended in order to achieve complete and curative resection (28). For larger tumors, formal pancreatoduodenectomy including lymphadenectomy might be required.

Neuroendocrine Neoplasia of the Liver

Despite the liver being the predominant site of neuroendocrine tumor metastases, primary NEN arising within the liver are rare. In a study of 13 715 carcinoid tumors accumulated by the National Cancer Institute in Bethesda over a 50-year period, only 45 primary hepatic tumors were documented [43]. Prior to the assumption that a hepatic NEN presents a primary lesion, a meticulous search for extrahepatic tumor manifestation is pivotal for effective management of such patients.

Patients with these tumors present with nonspecific hepatic clinical syndromes such as biliary obstruction or upper abdominal discomfort. In contrast to

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. neuroendocrine liver metastases, flushing, diarrhea, bronchial constriction, and carcinoid heart syndrome, which are pathognomonic for the classic carcinoid syndrome, will be found in only about 5% of cases [43]. On transabdominal ultrasound, the tumor appears as a hyperechoic lesion, although the appearance on radiologic imaging is not characteristic.

The treatment strategy comprises several curative and palliative options including surgery, locally destructive techniques such as radiofrequency or laser-induced thermoablation, transarterial embolization alone or with chemotherapy, selective internal radiotherapy, somatostatin analogues, targeted medical therapy, and peptide receptor radionuclide therapy. In contrast to the poor overall five-year survival of 18.4% reported in early studies [43], a more radical surgical approach including advanced hepatic resections or liver transplantation in selected cases and multimodal treatment concepts achieve three-year disease-free survival rates of more than 75% [44].

Neuroendocrine Neoplasia of the Extrahepatic Biliary Tract

These very unusual neoplasia account for 0.2–2% of all gastrointestinal neuroendocrine tumors [45]. In approximately 60% of patients, the tumor develops within the common bile duct [46]. Further locations are the perihilar region (28%), cystic duct (11%), and common hepatic duct (3%). Unlike adenocarcinomas of the extrahepatic biliary system, biliary NEN predominantly affects female patients younger than 50 years. The symptom most frequently seen is painless jaundice with or without pruritus. The diagnostic work-up spectrum includes US, CT, magnetic resonance cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP), and percutaneous transhepatic cholangiography. For tumor staging purposes, somatostatin receptor-based imaging provides valuable information.

As in other tumors originating from the biliary system, accurate preoperative diagnosis remains difficult, particularly regarding delineation from cholangiocarcinoma. Upon microscopic examination, the tumors present with a trabecular or nesting pattern with occasional tubule formation, and cells expressing CgA, synaptophysin, serotonin, pancreatic polypeptide, and/or somatostatin. Whereas local invasion is not common, metastatic lymph node involvement and liver metastases can be found in 30% of patients [47].

An aggressive surgical approach provides an overall favorable long-term prognosis. In early tumor stages and in the absence of metastases, five-year survival of 60–100% has been documented [48]. The extent of resection depends mainly upon the size, stage, and location of the tumor. Common bile duct resection and Roux-en-Y hepaticojejunostomy is the standard treatment of choice for lesions within the central portion of the common bile duct. For tumors affecting the hepatic duct bifurcation, resection of the bifurcation, in some cases in combination with partial hepatectomy, is necessary. Tumors of the distal part of the common bile duct require either segmental bile duct resection or partial pancreaticoduodenectomy (Whipple procedure). Extensive hilar lymphadenectomy is a mandatory part of the procedure.

Neuroendocrine Neoplasia of the Gallbladder

Approximately 0.2% of all NEN of the gastrointestinal tract originate from the gallbladder [49]. They usually affect females, causing right upper abdominal discomfort and jaundice. As in NEN of the extrahepatic biliary tree, the diagnosis is frequently made first after surgery for presumed cholecystitis or adenocarcinoma of the gallbladder although specific features on imaging helping to delineate them from adenocarcinoma have been reported [50]. Histologically, the tumor cells are positive for Grimelius staining and CgA, and less commonly for NSE or pancreatic polypeptide.

Although laparoscopic resection might be feasible in a small NEN confined to the wall of the gallbladder, the majority of the patients, particularly those with NEC, require a more radical surgical approach in terms of hepatic resection, removal of the extrahepatic bile duct, and extended hilar lymphadenectomy. An overall five-year survival of approximately 60% has been reported [43].

Introduction

Pancreatic neuroendocrine neoplasm (PanNENs), representing 1–2% of pancreatic neoplasms, comprise an array of heterogeneous, mostly slow-growing tumors. Over recent decades, PanNEN incidence has persistently increased due to early detection of localized and asymptomatic tumors made possible by highly sensitive and specific imaging modalities. This wide spectrum ranges from indolent, hormone-secreting, localized, and easily accessible tumors to nonfunctioning, widely metastatic, and surgically less amenable tumors, at various time points on the tumor growth trajectory. These tumors may differ in tumor entity, clinical presentation (symptomatic versus asymptomatic), hormone secretion (functioning versus nonfunctioning), genetic background (sporadic versus hereditary), anatomic location (pancreatic head versus body and tail; anterior versus posterior pancreas), staging (primary tumor size, lymph node metastasis, and distant metastases), and grading (well-differentiated versus poorly differentiated PanNENs). Given the longevity of many patients with PanNENs, many observation periods were different in duration and the intensity of clinical monitoring.

Because treatment must be commensurate with the extent of disease, surgical and nonsurgical patients from selected groups defy standardization of therapy. Many series lumped together disparate endocrine tumors and no high-quality outcome studies have been forthcoming for any of these scenarios, leaving univariate risk factors unvalidated. Although some general principles have emerged from institutional series and tumor registries, the role and extent of surgery remain to be delineated for a number of clinical settings.

Risk Stratification of Pancreatic Neuroendocrine Neoplasm

Tumor Staging

In 2006, the European Neuroendocrine Tumor Society (ENETS) developed the first staging system for neuroendocrine tumors from the combined published experience of single centers at the level of the neuroendocrine tumor patient. A competing staging system, derived from a cancer registry database by the International Union Against Cancer, now the Union for International Cancer Control (UICC), in 2010 and now endorsed by both the American Joint Committee on Cancer (AJCC) and the World Health Organization (WHO), followed suit (henceforth referred to as the UICC/AJCC/WHO TNM). Disease stage and tumor grade are the two major independent prognostic parameters.

It is noteworthy that the UICC/AJCC/WHO TNM, unlike the ENETS TNM, is the same as for exocrine pancreatic tumors and not meant for high-grade PanNETs. As a consequence, tumor definition and stages differ greatly between the ENETS TNM and UICC/AJCC/WHO TNM staging systems. Of note, the UICC/AJCC/WHO TNM requires information on peripancreatic soft tissue invasion regardless of tumor size, a feature difficult to assess, to distinguish between UICC/AJCC/WHO categories pT2 and pT3.

The newly revised AJCC 8th edition staging system introduces the classification criteria asserted by ENETS and shows several significant changes. First, the PanNEN staging system is a separate system and applies only to G1 (ENETS/WHO 2019 grade 1), G2 (ENETS/WHO 2019 grade 2), and well-differentiated G3 tumors

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

Companion website: www.wiley.com/go/beger/thepancreas4e

(ENETS/WHO 2019 grade 3) The remaining poorly differentiated G3 (ENETS grade 3) neuroendocrine carcinoma follows staging of exocrine pancreatic cancer. Second, the size of the tumor has become an important criterion to distinguish the T category and invasion of soft tissue around the pancreas was excluded from staging criteria. Third, adjacent organ invasion has been categorized as T4, together with unresectable cases such as major vascular invasion. Fourth, the M1 category has been included according to metastatic sites. A recent study proved that the AJCC 8th edition staging system for PanNETs provides better discrimination compared to the 7th edition and ENETS TNM system [1].

Disease-free Survival

A recent study compared the AJCC system to the ENETS system by analyzing 472 patients who had undergone surgery for PanNETs [1]. The disease-free survival (DFS) curves of the 8th AJCC classification were well separated between all stages. Compared with stage I, the hazard ratio of II, III, and IV was 3.808, 13.928, and 30.618, respectively (P = 0.007, P <0.001, and P <0.001). In the ENETS staging system, there was no significant difference in DFS between stage IIB versus IIIA (P = 0.909) and IIIA versus IIIB (P = 0.291).

Overall Survival

One hundred and sixty five eligible patients with surgically resected PanNEN were evaluated to investigate the prognostic value of the two systems—ENETS and AJCC. Using the ENETS classification, the overall survival (OS) rate differences of patients with functional PanNETs were statistically significant when comparing stage I with stages III and IV (I vs III, P <0.001; I vs IV, P <0.001), as well as stage II and stages III and IV (II vs III, P = 0.009; II vs IV, P <0.001); differences in OS of stage I with II or stage III with IV were not significantly different (I vs II, P = 0.409; III vs IV, P = 0.499). Using the AJCC criteria, only patients with stage I functional tumors showed a significantly better OS rate than those with stage III and IV tumors (I vs III, P <0.001; I vs IV, P <0.001), while there were no significant differences when comparing patients in stages I and II, stages II and III, stages II and IV and stages III and IV (all P >0.05). Similarly, using the ENETS system to compare patients with nonfunctional tumours, stages I, II, and III had a significantly better survival than those with stage IV tumors (I vs IV, P = 0.005; II vs IV, P <0.001; III vs IV, P = 0.026). However, there were no OS differences when comparing patients in stage I with those in stages II and III, or between those in stages II and III (all P >0.05) [2]. The ENETS system might have potential advantages when applied to all PanNETs and to the functional subgroup, while the AJCC system might be clinically more practical for nonfunctional PanNETs.

Tumor Grading

Since the WHO 2010 classification, PanNENs have been graded according to Ki-67 index and mitotic count. The 5th edition of the WHO classification of digestive system tumors published in 2019 discussed advancements that have been made in the understanding of etiology and pathogenesis of several digestive system tumors. The 2019 WHO classification relies mainly on histopathologic criteria, including Ki-67 proliferative index and mitotic index, to predict the tumor's grade and biological behavior. There is no upper limit to the proliferation index of NET G3, and the degree of cell differentiation is one of the key points of differentiation.

Using this stratification system, PanNENs are classified as well-differentiated NET and poorly differentiate NEC. In addition, well-differentiated NET is further subdivided into "well-differentiated low-grade NET (G1)," "well-differentiated intermediate-grade NET (G2)," and "well-differentiated high-grade NET (G3)." The current WHO classification includes three grades (G1, G2 and G3) for NETs. NECs are no longer graded, as they are recognized to be uniformly high grade by definition, but continue to be separated into small and large cell types [3]. NETs are graded into G1, G2, and G3 based on the proliferation activity assessed by mitotic rate and/or Ki-67 proliferation index.

An important change in the 8th edition of the AJCC system is that G3 was not included in the PanNET staging system, unlike the previous ENETS system. This reflects the results of previous studies showing that exocrine tumors and neuroendocrine tumors have different tumor biology and prognosis [1].

The current WHO classification for endocrine organs (WHO 2019) was devised for PanNETs alone. This classification endorses the WHO 2010 principles, but introduces the definition of NET G3 for neoplasms that are well differentiated in morphology but display a proliferation index in the G3 range. WHO 2017 and 2019 classifications split the heterogeneous G3 gastroenteropancreatic (GEP)-NENs into well-differentiated NET G3 and poorly differentiated NEC. Clinical history, histomorphology, and genetics (*DAXX/ATRX/MEN1* mutation in Pan-NET G3, *p53* mutation or *RB* loss in NEC G3) help in separating the groups.

Another important change concerns the recognition that well-differentiated NETs may be high grade (G3 in the WHO grading system, defined as having a mitotic rate >20 per 2 mm^2 or Ki-67 >20%), but these neoplasms

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

remain well differentiated genetically and distinct from poorly differentiated NECs. G3 NETs were first recognized and are most common in the pancreas, but they can occur throughout the gastrointestinal tract. The WHO 2019 classification strongly emphasizes the association of well-differentiated morphology with the NET definition, and poorly differentiated morphology with the NEC definition. The 2019 WHO grading, based on the mitotic count (<2, 2–20, and >20 mitoses per 10 high-power fields) and the Ki-67 index (<3%, 3–20%, and >20%), holds important prognostic information, especially in the absence of staging information.

Surgical Considerations for Pancreatic Endocrine Tumors

While multiple treatment options exist for PanNETs, a recent study showed that surgical resection is indicated for localized PanNETs that are >1–2 cm, grade 2, symptomatic, functional, or with evidence of regional lymph node metastases in patients who are acceptable candidates for pancreatectomy [4]. Preoperative evaluation of localized PanNETs should consider tumor size, the presence of unspecific symptoms, functional activity, localization of the lesion, and signs of local invasiveness.

Unlike functional PanNETs presenting with signs and symptoms of hormone excess, nonfunctioning PanNETs do not produce identifiable symptoms. Some clinically "nonfunctioning" tumors synthesize hormones in quantities too low to elicit complaints (e.g., glucagonoma) or hormones unable to produce symptoms in humans (e.g., pancreatic polypeptide). Because curative surgery determines survival more than tumor stage, the patient's clinical outcome hinges on the feasibility of complete tumor resection.

Several studies have demonstrated the safety of a "watch and wait" strategy instead of surgery for asymptomatic NF PanNETs ≤2 cm [5,6]. Surgery is recommended for young patients and in cases where signs of local invasiveness (e.g., dilation of the main pancreatic duct and/or presence of jaundice and/or suspicion of nodal involvement) are present. In the latter condition, a standard pancreatectomy with lymphadenectomy is recommended, whereas a parenchyma-sparing resection (e.g., enucleation or central pancreatectomy) should be routinely considered when the indication for surgery is related to long life expectancy. Moreover, surgery is mandatory in the presence of functioning PanNETs irrespective of tumor size. Curative resection of localized PanNETs seems generally associated with improved long-term survival and a low risk of recurrence [7].

A standard pancreatectomy (pancreaticoduodenectomy or distal pancreatectomy) with regional lymphadenectomy is recommended for PanNENs >2 cm [8]. Enucleation may represent an alternative approach to standard pancreatectomy in selected cases [9]. Functioning PanNENs such as insulinomas <2 cm represent ideal lesions to be enucleated, given that they are safely distant from the main pancreatic duct. Other functioning PanNENs are recommended for standard surgical methods. The role of enucleation for NF-PanNENs is currently limited to selected patients with small lesions in whom a "watch and wait" approach is contraindicated.

Nonfunctioning Tumors

Localized Tumors

A tumor size of 2 cm is the cut-off value proposed by current international guidelines as the main criterion of choice between conservative management and a surgical approach in asymptomatic patients with sporadic NF-PanNETs [6]. Zhang et al. retrospectively evaluated a large single-institution experience of patients with NF-PanNETs and found that surgery was significantly associated with improved survival, although this effect disappeared when tumors were <1.5 cm [10]. In a systematic review, Partelli et al. found observation to be a safe strategy for small NF-PanNETs with no disease-related mortality among patients initially undergoing active surveillance. In this study, 14% of patients who chose initial observation ultimately underwent surgical resection: 41% for tumor growth, 39% because of patient preference, and 15% for physician preference [5].

Unifocal Tumors

Localized tumors are easier to cure surgically when they are small, stay clear of large vessels and the bile duct, and involve only the anterior aspects of the pancreas, preferably the body or tail. To develop an effective surgical treatment plan, a thorough clinical work-up is essential to settle these important points before the operation and ensure that no additional tumors are missed.

There are basically three surgical techniques, each of which may be adequate depending on the circumstances of the case: tumor enucleation (leaving peritumoral tissue behind); excision (clearing peritumoral tissue together with the tumor); and pancreatic resection, which is bound to vary greatly in extent and scope depending on tumor location and type. Pancreatic surgery that leaves gross tumor behind is unlikely to benefit the patient. In patients without distant disease, every effort should be made to clear the mesenteric vessels of malignancy.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Multifocal Tumors

When additional endocrine tumors are present or the family history is suggestive of hereditary disease, specifically multiple endocrine neoplasia type 1 (MEN 1) or von Hippel–Lindau syndrome (VHL), the surgical plan needs to be adjusted accordingly. Intraoperatively, the pancreas should be mobilized to allow for careful examination of the posterior aspect of the organ. Owing to the variety of constellations conceivable, multiple tumors are notoriously difficult to standardize, hampering predictions about clinical outcome.

Metastatic Tumors

Lymph Node Metastases

Studies have previously demonstrated that the risk of lymph node or distant metastasis in resected well-differentiated PanNETs progressively increased based on tumor size, including rates of 18% and 11%, respectively, for tumors measuring 1–2 cm [11].

A multiinstitutional study found that the rate of lymph node metastasis and tumor recurrence was higher for tumors measuring 1.5–2.0 cm compared with tumors measuring 1.0–1.5 cm [12]. These data hint at an interrelation between primary tumor size, lymph node metastasis, and liver metastasis, which signifies increasing cancer-specific mortality for these three risk factors.

Distant Liver Metastases as the Sole Systemic Manifestation

The debate over observation versus resection for well-differentiated NF-PanNETs is based on the uncertain potential for regional or metastatic spread compared with the potential morbidity of pancreatic surgery. Surgical resection may even be indicated in the setting of locally advanced disease requiring vascular resection or liver metastases amenable to liver resection/ablation [13,14].

Several retrospective studies have focused on liver metastases, the predominant manifestation of systemic disease, as the sole clinical appearance of PanNET. In 291 patients with poorly differentiated PanNETs, distant metastasis (hazard ratio [HR] 2.41; P <0.001), lymph node metastasis (HR 2.10; P = 0.004), and poor differentiation (HR 6.96; P = 0.032) were independent predictors of worse survival, with distant metastasis having a significant impact (0% versus 43%; P = 0.036) on five-year overall survival [15]. Enucleation of hepatic metastases, leaving surrounding parenchyma behind, is associated with greater short-term morbidity than hepatic resection, which entails the excision of metastases together with the surrounding liver parenchyma.

In light of these data, it is challenging to conduct head-to-head comparisons between enucleation of and hepatic resection for liver metastases from PanNETs. To facilitate surgical decisions, information about the biological behavior of the PanNET at hand (low versus high risk) is needed. According to current thinking, debulking needs to reduce the liver tumor burden by as much as 90% to improve outcome [16]. In some patients, total hepatectomy with subsequent liver transplantation has been used. Liver resection has been shown to improve symptom relief and survival compared with nonsurgical therapy [17].

Widespread Systemic Disease

Surgery with curative intent is indicated for PanNETs with liver metastases, provided there is absence of extrahepatic metastases, diffuse bilobar liver involvement, or compromised hepatic function. However, the majority of PanNETs present with unresectable stage IV disease, and the benefit of surgery to the primary lesion, particularly in asymptomatic nonsecretory tumors, remains controversial. Palliative resection of NF PanNETs requires potentially morbid surgery and is not widely recommended, despite emerging data demonstrating a similar survival benefit in this cohort [18].

Functioning Tumors

In general, all sporadic, localized F-PanNETs should be resected in patients healthy enough for surgery. Whereas NF tumors often become clinically apparent through complaints caused by tumor expansion, invasion, or metastatic disease, functional tumors, such as insulinoma, gastrinoma, and vasoactive intestinal peptide-releasing tumor (VIPoma), tend to be diagnosed at earlier stages when they present with signs and symptoms of hormone excess. Hormone excess typically produces clinical complaints that are more debilitating and diminish health-related quality of life more than those produced by tumor expansion, invasion, or metastatic disease. Hormonal symptoms cannot resolve if secondary hormone-secreting tumors are missed on enucleation or pancreatic resection, usually in hereditary conditions, or may occur again, if the resection is inadequate, failing to remove the tumor in its entirety.

Insulinoma

Surgery is generally recommended for insulinomas; when indicated, a minimally invasive approach is preferable. Pancreatectomy with lymphadenectomy is recommended for malignant insulinomas [19]. Because it almost always is benign, insulinoma forms an ideal surgical target for enucleation. Surgical cure rates for insulinoma are excellent, approaching 99% in experienced hands. In patients

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with insulinoma, the clinical–histopathologic risk profile is heavily stacked in favor of surgical cure: small tumors, benign in nature; young patients with few, if any, comorbidities; enucleation or very limited pancreatic resection required only. Insulinomas have low malignant potential and thus pancreas-preserving approaches without routine lymphadenectomy are generally sufficient and are associated with high rates of biochemical cure and low rates of recurrence. A recent study showed that the 10- and 15-year disease-free rates of insulinoma after surgery were 95.6% and 85.4%, respectively [20].

Gastrinoma

For gastrinomas, the high malignant potential is assumed, and resection with lymphadenectomy is recommended. Gastrinomas with MEN 1 exhibit metachronous recurrences, so care must be taken to avoid excessive surgery [21].

Formal pancreatectomy with regional lymph node resection is recommended. For example, regional lymph node dissection for gastrinoma is associated with improved biochemical cure and potentially survival.

Glucagonoma, Somatostatinoma, and VIPoma

As rare functional pancreatic NENs other than insulinomas and gastrinomas (e.g., glucagonomas, VIPomas, somatostatinomas, GRFomas, PPomas, ACTHomas, and PTHomas) are highly malignant, pancreatectomy with lymphadenectomy is recommended [22]. Most glucagonomas and somatostatinomas are considered "nonfunctional" even when they present with characteristic signs and symptoms, as with necrolytic migratory erythema, which is pathognomonic of glucagonoma. Somatostatinomas, lacking characteristic stigmata, are often so large at the time of diagnosis that they can no longer be enucleated. VIPoma typically causes Verner–Morrison syndrome, which is characterized by watery diarrhea, hypokalemia, and achlorhydria (WDHA). These tumors, being the subject matter of single reports or small case series, are extremely rare, precluding the generation of comprehensive evidence-based data.

Conclusion

Although great strides have been made in terms of staging and grading of PanNEN, it has proved challenging to assemble large enough series of patients with PanNEN and sufficiently long follow-up periods to permit the adjustment of postoperative outcomes for a large number of confounding variables: tumor entity, clinical presentation, hormone secretion, genetic background, location within the pancreas, tumor stage and grade, type and extent of surgery, surgical margins, and neoadjuvant and adjuvant therapies. There is a dire need for predictive molecular markers that afford better risk stratification of PanNETs than currently provided for by Ki-67 grading and current imaging modalities.

Epidemiology of Pancreatic Cancer

Evelina Mocci and Alison P. Klein

Departments of Oncology and Epidemiology, Sidney Kimmel Comprehensive Cancer Center, Johns Hopkins School of Medicine, Baltimore, MD, USA

Incidence, Mortality Trends, Survival Prognosis

In 2020, worldwide, there were approximately 495 773 individuals diagnosed with pancreatic cancer and approximately 466 003 individuals died from their disease, making pancreatic cancer the seventh most common cause of cancer death [1]. Pancreatic cancer is strongly associated with increased age, with the majority of cases occurring after age 60. In the United States, from 2014–2018 the incidence of pancreatic cancer in whites increased from 3 per 100 000 or less before age 45, to 33.4 per 100 000 in individuals aged 60–64, and 97.3 per 100 000 in individuals aged 80–84 [2]. Incidence is approximately equal in men and women. The disease burden is strongest in developed countries compared to developing countries [1]. This difference is likely driven, in large part, by differences in age structure as well as access to medical care necessary for the diagnosis of pancreatic cancer [3].

In developed countries, the overall incidence of pancreatic cancer is expected to continue to increase with the general aging of the population, particularly in high-income countries [4,5]. Pancreatic cancer is projected to become the second leading cause of cancer death in the United States by 2030 [6]. However, other countries have seen a recent decrease in the incidence of pancreatic cancer that seems to reflect patterns in cigarette consumption. As discussed later, cigarette smoking is a major risk factor for pancreatic cancer and never smoking or smoking cessation is strongly associated with a decrease in risk. In contrast, increased body mass index (BMI) and diabetes mellitus are both associated with a greater risk of pancreatic cancer and the increasing prevalence of these risk factors is projected to lead to a rise in incidence of pancreatic cancer.

Pancreatic cancer is associated with an extremely poor prognosis with an estimated average and a five-year rate of ~10% in the US [4]. Survival rates have increased only slightly since the mid-1970s, from 4–5% to around 10% in the United States [2]. The low survival rates are mainly due to advanced stage at diagnosis, with only ~33% of patients presenting with local disease [2]. Among patients who undergo surgical resection, the five-year survival rate is ~15–25% [7]. Outcomes after surgical resection of the pancreas are highly dependent on the experience of the surgeon and the hospital; mortality rates are 70% lower among high-volume surgeons compared with low-volume surgeons, and hospitals with a high patient volume compared with low-volume hospitals [8].

Cigarette Smoking

Of modifiable risk factors, the relationship between active cigarette smoking and pancreatic cancer risk is well established. Approximately 20% of all pancreatic cancers are attributable to cigarette smoking [9–11]. Numerous studies have explored the relationship between smoking and pancreatic cancer. A metaanalysis of 82 epidemiologic studies published between 1950 and 2007 [9] reported a 1.74-fold (95% confidence interval [CI] 1.61–1.87) increased risk of pancreatic cancer among current smokers and a 1.2-fold (95% CI 1.11–1.29) increased risk of pancreatic cancer among former smokers when compared with never smokers. Pooled analysis of individual-level data from the nested

Companion website: www.wiley.com/go/beger/thepancreas4e

case–control studies within the Cohort Consortium (PanScan) [11] as well as analysis of data from 12 case–control studies in the Pancreatic Cancer Case-Control Consortium (PanC4) [10] showed that smokers have a 75–120% increased risk of pancreatic cancer compared with never smokers, and the risk persists for 10–20 years after smoking cessation [10,11]. Risk also increased according to the number of cigarettes consumed per day; smokers of more than 35 cigarettes per day have a threefold (95% CI 2.2–4.1) increased risk of pancreatic cancer compared with never smokers [10].

Quitting smoking is associated with a reduced pancreatic cancer risk with a decreased odds ratio in former smokers when compared with active smokers. Studies suggest that the risk in former smokers returns to that of never smokers 15–20 years after smoking cessation [10,11].

Diabetes

The relationship between diabetes and pancreatic cancer is quite complex; many newly diagnosed pancreatic cancer patients report a recent onset of diabetes, and those with long-standing diabetes report a recent worsening of diabetes. Thus, it is generally considered that while long-standing diabetes is a risk factor for pancreatic cancer, diabetes can also result as a consequence of pancreatic cancer.

There is considerable variability when estimating the prevalence of diabetes and/or glucose intolerance among newly diagnosed pancreatic cancer patients [12]. It has been estimated that up to 80% of newly diagnosed pancreatic cancer patients have glucose intolerance or diagnosed diabetes [13]. Studies that rely on patient or medical records of reported diabetes show lower prevalence estimates, including a large Mayo Clinic case–control study in which 40% of patients reported diabetes [14]. Over 75% of pancreatic cancer patients who develop diabetes, do so within the two years preceding their pancreatic cancer diagnosis [15]. Thus, there is considerable interest in examining populations of newly diagnosed diabetics to determine whether this might enable earlier detection of pancreatic cancer. While initial studies have indicated that up to to 1% of newly diagnosed diabetics develop pancreatic cancer within three years of their diabetes diagnosis [16], subsequent studies have shown a lower incidence of <0.3% [17].

While many pancreatic cancer patients develop diabetes as a consequence of their disease, there is considerable support from numerous population-based studies that long-standing diabetes (>3 years) is associated with a modest increase in the risk of pancreatic cancer. Overall, the risk of pancreatic cancer in long-standing diabetes ranges from 1.5- to 2.4-fold [18–21]. However, as the duration of diabetes increases, the association between diabetes and pancreatic cancer weakens, with some studies showing only modest or no increase in pancreatic cancer risk 15–20 years after diagnosis with diabetes [21,22]; however, some studies still support an association with diabetes of 20 years or more [20].

In patients with new-onset diabetes who undergo surgical resection, diabetes often resolves after removal of the pancreatic cancer. In contrast, diabetes does not resolve in patients with long-standing diabetes after surgical removal of their cancer [23].

Body Mass Index

In addition to diabetes, increased weight or BMI has consistently been associated with increased risk of pancreatic cancer. The World Health Organization (WHO) defines overweight individuals as those with a BMI of 25.0–29.9 kg/m^2 and obese individuals as those with a BMI >30.0 kg/m^2.

Over the past 15 years, many studies have demonstrated an increased risk of pancreatic cancer among obese individuals. In 2001, Michaud et al. reported a relative risk of pancreatic cancer of 1.72 (95% CI 1.19–2.4) for individuals with a BMI >30 kg/m^2 compared with individuals with a BMI <23 kg/m^2 after controlling for the effect of age, smoking, and diabetes among participants of the Health Professionals Follow-Up Study and the Nurses' Health Study [24]. Many subsequent studies have confirmed this finding; a pooled analysis of data from 13 prospective cohort studies reported an odds ration (OR) for pancreatic cancer of 1.33 (95% CI 1.12–1.58) when comparing individuals in the lowest quartile of BMI with those in the highest quartile after controlling for the effects of age and smoking. Adjusting for the effect of diabetes attenuates this association slightly (OR 1.21; 95% CI 1.01–1.44) [25].

Alcohol

Numerous studies have examined the association between alcohol consumption and risk of pancreatic cancer. The results of these studies have been inconsistent, with some studies showing an association and others showing no relationship. One challenge to these studies is the strong relationship between smoking and heavy alcohol use, making it difficult to assess the independent association between alcohol use and pancreatic cancer risk. However, several recent large-scale studies that have pooled data across several studies, using data from either prospective

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cohort studies or retrospective case–control studies, have demonstrated that high levels of alcohol intake are associated with an increased risk of pancreatic cancer. These studies consistently report a ~20–45% increased risk of pancreatic cancer among heavy drinkers (defined as three drinks/day or ≥30 grams/day of alcohol), compared with non- or occasional drinkers [26–28]. In addition, in a pooled analysis of data from the Pancreatic Cancer Case-Control Consortium [29], the risk increases up to 60% among extremely heavy alcohol drinkers (≥9 drinks/day).

Heavy alcohol consumption is associated with pancreatitis, an established risk factor for pancreatic cancer. Furthermore, acetaldehyde is an established carcinogen. Thus, the association between alcohol and pancreatic cancer risk could be either via alcohol-induced pancreatitis or as a direct effect of acetaldehyde.

Pancreatitis

The relationship between pancreatitis and pancreatic cancer has been well established. Individuals with hereditary pancreatitis, a rare inherited condition, have a remarkably high lifetime risk of pancreatic cancer of 40% [30]. The risk is further increased by cigarette smoking [31]. Quantifying the association between pancreatitis and pancreatic cancer is challenging given the difficulties in diagnosis and differentiation between chronic and acute pancreatitis [32]. In addition, like diabetes, pancreatitis is both a risk factor and a manifestation of pancreatic cancer.

The inflammation and damage of long-standing pancreatitis can lead to the development of pancreatic cancer. However, individuals with pancreatic cancer also experience pancreatitis as a consequence of their cancer. A recent large-scale study of 5048 cases of ductal pancreatic adenocarcinoma and 10 947 controls from 10 case–control studies within the Pancreatic Cancer Case-Control Consortium examined the association between pancreatic cancer and pancreatitis. Overall, 6% of pancreatic cancer patients reported a history of pancreatitis compared to 1% of control individuals. The association between a recent diagnosis of pancreatitis (<1 year) and pancreatic cancer was remarkably high (OR 21.35; 95% CI 12.03–37.86) [33]. In contrast, the association between pancreatitis and pancreatic cancer was nearly threefold at intervals of >2 years between diagnoses (OR 2.71; 95% CI 1.96–3.74 [33]. The association between pancreatitis and pancreatic cancer persisted after controlling for other risk factors including smoking, alcohol consumption, BMI, and diabetes. Interestingly, there was evidence of effect modification by age, with a stronger association between pancreatitis and pancreatic cancer in patients diagnosed before the age of 65 [33].

Dietary Factors

Given the generally late age of onset of pancreatic cancer and the complexity of lifetime dietary factors, identification of dietary factors that are consistently associated with pancreatic cancer risk has been remarkably challenging. Several studies have suggested a diet rich in fruit and vegetables may protect against pancreatic cancer with risk reduction in the order of 30–40%, when comparing the highest intake to the lowest intake of fruits and vegetables [34–36]. While a diet rich in fruit and vegetables may protect against pancreatic cancer, several studies have demonstrated an increased risk of pancreatic cancer among individuals who are frequent consumers of smoked or processed meats [37]. A metaanalysis including 6643 pancreatic cancer cases from 11 prospective studies reported that eating at least one serving of processed meat a day was associated with a 19% increased risk of pancreatic cancer [37].

Gastrointestinal Microbiome

In recent years, the importance of the microbiome in human health and disease has gained recognition. Several studies have shown that periodontal disease and tooth loss are associated with pancreatic cancer risk [38]. In 2007, a study among males participating in the Health Professionals Follow-up Study reported that individuals with a history of periodontal disease had a hazard ratio (HR) of pancreatic cancer of 1.54 (95% CI 1.16–2.04) compared with those without such a history [39]. A recent study examined the association between specific oral pathogens and pancreatic cancer risk using prospective samples collected within the PLCO trial. This study found that individuals with circulating antibodies to *Porphyromonas gingivalis* and *Aggregatibacter actinomycetemcomitans* had higher odds of pancreatic cancer (OR 1.60; 95% CI 1.15–2.20, and OR 2.20; 95% CI 1.16–4.18, respectively), compared with noncarriers [40].

While some studies have shown an association between pancreatic cancer risk and *Helicobacter pylori* infection, not all studies have shown a positive association. One possible explanation for these inconsistent results is that the relationship may vary between CagA-positive and CagA-negative infections; CagA-negative infection is positively associated with disease and CagA-positive infection potentially has a protective effect. A recent metaanalysis found an overall association of OR 1.13; 95% CI 0.86–1.50 for *H. pylori* infection an pancreatic cancer risk. The association was OR 0.78; 95% CI 0.67–0.91, and OR 1.30; 95% CI 1.02–1.65 for CagA-positive and CagA-negative strains, respectively [41].

Allergy

Individuals with a history of allergies, including hay fever, allergic rhinitis, atopic dermatitis, and atopic asthma, may have a lower risk of developing pancreatic cancer. A metaanalysis published in 2005 reported an overall association between allergies and pancreatic cancer risk of relative risk (RR) 0.82; 95% CI 0.68–0.99. A stronger protective effect was reported in atopic allergies (RR 0.71; 95% CI 0.64–0.80) and no association was reported for asthma or food allergies [42]. A recent pooled analysis of data from the Pancreatic Cancer Case-Control Consortium reported a protective effect of hay fever and animal allergies (OR 0.74; 95% CI 0.56, 0.96, and OR 0.62; 95% CI 0.41, 0.94, respectively), and no association with asthma [43]. In contrast, a recent case–control study from Spain reported a protective effect of both allergy and asthma (OR 0.66; 95% CI 0.52–0.83, and OR 0.64; 95% CI 0.47–0.88, respectively) [44].

Family History

One of the strongest risk factors for pancreatic cancer is having a family member with pancreatic cancer. The clustering of pancreatic cancer in families was first reported in the 1970s. Large-scale observational studies have consistently estimated an increased risk of pancreatic cancer among those with a family history of pancreatic cancer [45–53]. A recent pooled analysis of data from one case–control and six cohort studies estimated the odds of pancreatic cancer to be 1.76 higher (95% CI 1.19–2.61) among individuals who had at least one first-degree relative with pancreatic cancer compared with those with no family history of pancreatic cancer [51]. Risk is even higher in familial pancreatic cancer kindreds (defined as a having at least one pair of first-degree relatives with pancreatic cancer) with a 6.79-fold increased risk of pancreatic cancer among first-degree relatives. Mutations in the following genes have been associated with a markedly increased risk of pancreatic cancer: *BRCA2*, *BRCA1*, *PALB2*, *ATM*, *CDKN2A*, *STK11*, *PRSS1*, *MSH2*, *MLH1*, *MHS6*, and *PMS2* [54–60].

Conclusion

Pancreatic cancer is a leading cause of cancer mortality in developed countries. Unlike other cancers, the incidence of pancreatic cancer has increased in recent years. Major modifiable risk factors include cigarette smoking, diabetes, obesity, and alcohol intake. Nonmodifiable risk factors include age and family history of pancreatic cancer.

Smoking, a Risk for Pancreatic Cancer: Experimental and Clinical Data

Uwe A. Wittel[1], Bradley R. Hall[2], and Surinder K. Batra[3]

[1] *Department of General and Visceral Surgery, Universitätsklinikum Freiburg, Freiburg, Germany*

[3] *Department of Biochemistry and Molecular Biology, University of Nebraska Medical Center, Omaha, NE, USA*

Introduction

Smoking is a well-established, avoidable risk factor accounting for approximately 16% of pancreatic cancer cases in Europe [1]. The increase in cancer risk is dose dependent but a long duration at lower intensity seems to be worse than a higher intensity over a shorter period of time and the use of a small daily number of cigarettes is sufficient to sharply increase the pancreatic cancer risk [2]. Interestingly, smoking is not associated with the transformation of intraductal papillary mucinous neoplasms (IPMNs) to invasive IPMN, indicating different pathways between IPMN transformation and developing pancreatic ductal adenocarcinoma [3]. While clear epidemiologic associations exist between inhaled cigarette smoke and pancreatic disease, our ability to delineate this association remains limited. Of note, no similar association has been demonstrated between smokeless tobacco and pipe or cigar smoking and pancreatic cancer.

Experimental Data Regarding Smoking: A Risk Factor for Pancreatic Cancer

Due to the large number of chemicals in cigarette smoke, the effect of cigarette smoke on the pancreas is likely multifactorial and complex. Several of these chemicals display toxic, carcinogenic, or pharmacologically active properties, of which many have not yet been identified, contributing to our incomplete understanding on the effects of cigarette smoking on the pancreas.

This problem was addressed by several experiments utilizing *in vivo* treatment with tobacco smoke or *in vitro* treatment with cigarette smoke condensate. Several effects of cigarette smoking observed in humans could be reproduced experimentally. *In vivo* experiments demonstrated that smoking induced pancreatic inflammation and sustained endothelin upregulation as well as mitochondrial dysfunction [4,5]. *In vitro*, cigarette smoke extracts induced oncogenic AKT signaling by the induction of maturation of miR-25-3p, a complex mechanism linking cigarette smoking to pancreatic cancer development [6]. Furthermore, cigarette smoke extracts induced stem cell features in cancer cells via 7α nAChR-mediated PAF1 expression [7]. In contrast to cancer-inducing pathomechanisms, cigarette smoke extracts increased the protective properties of pancreatic cells by increasing intracellular glutathione by NFκB activation, thus increasing the protection against radical oxygen species [8].

Two mechanisms of action have been described for the compounds identified in cigarette smoke. First, chemicals such as polycyclic aromatic hydrocarbons have obvious carcinogenic properties that damage genomic DNA. Second, chemicals such as nicotine exert pharmacologic effects on cells, contributing to neoplasia.

Genetic analysis has revealed that the risk of a smoker developing pancreatic cancer is associated with the gene locus on 2q.21.3 in intron 5 of the transmembrane protein 163 (TMEM163) and upstream of the cyclin T2 (CCNT2) [9]. Once pancreatic cancer is developing, genetic alterations in 12 signaling pathways are found in over 67% of patients independent from cigarette smoking [10]. Some of these pathways include integrin signaling, apoptosis, DNA damage control, and regulation of the G1/S phase, to name a few. Carcinogens derived from cigarette smoke are likely contributing to genetic

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

alterations such as these. Following inhalation, carcinogens travel through the bloodstream to the pancreas where they are taken up by acinar or ductal cells. Once carcinogens reach their target tissue, they then begin to exert their toxic properties. For example, 80 days of oral 2-aminoanthracene, a member of the anthracene family, was found to induce pancreatic acinar cell necrosis with formation of duct-like structures [11]. Other carcinogens have to be metabolized to more active compounds before they exert their toxic properties, especially nitrosamines, nitroaromatic hydrocarbons, and aromatic and heterocyclic compounds which are metabolized to reactive electrophiles. These reactive electrophiles are then able to interact with DNA to exert their genotoxic carcinogenic effects [12,13].

Several enzymatic systems are available for pancreatic carcinogen metabolism, of which the cytochrome P450 system, glutathione S-transferases, and the UDP-glucuronosyltransferases are the most important. NNK (4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone), the most abundant and best studied carcinogen in cigarette smoke, undergoes CYP 450-dependent oxidation to form NNAL (4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol) whose S-enantiomer shows high adduct formation with pancreatic DNA [14]. This results in the creation of DNA adducts to either thymidine or guanine [15]. It can be postulated that these DNA adducts induce mutations and act as key steps in pancreatic cancer development if these mutations are randomly formed in critical gene loci such as *KRAS* or *P53*.

In addition to DNA mutations in critical loci, a disturbance of epigenetic regulation of gene expression can be induced by cigarette smoke through aberrant DNA methylation by benzo[a]pyrene, shown to be present in significantly high concentrations in cigarette smoke. This effect of aberrant DNA methylation has been previously demonstrated in the pancreas of mice treated with benzo[a]pyrene [16]. The carcinogen-induced DNA methylation can interfere with the expression of a variety of crucial genes in the pancreas.

Apart from their carcinogenic properties, compounds such as nicotine or NNK, NNN (N-nitrosonornicotine), and NDMA (N-nitrosdiethylamine) exert pharmacologic effects by functioning as ligands for cell surface receptors. These substances contained in cigarette smoke at high concentrations interact and activate nicotinergic acetylcholine receptors (nAChRs). These receptors are expressed not only on normal acinar and ductal cells but also on pancreatic cancer cells [17]. Each substance can be found in different concentrations in cigarette smoke, with nicotine demonstrating the highest concentration, followed by NNK and NNN.

In addition to the varying quantities of these chemicals, substantial discrepancies in binding affinities also exist. NNK preferentially binds to α7 nAChRs while NNN has a higher affinity for α2-α6 nAChRs [18]. This activation of nAChRs contributes to cigarette smoke-induced pancreatic carcinogenesis [17]. NNK not only activates nAChRs; by activating β2-AR signaling, it also induces HIF1 upregulation which then leads to increased proliferation of pancreatic cancer cells and increased pancreatic cancer cell invasion [19]. Benzapyrene and dioxine may also activate aryl hydrocarbon receptors, inducing IL-22 mediated pancreatic fibrosis [20].

Independent of pancreatic carcinogenesis, nicotine is associated with the development of pancreatic inflammation. The inflammatory effects of nicotine on acinar cells are thought to occur in a calcium-dependent mechanism. In isolated acinar cells, nicotine activates nAChRs, promoting the influx of calcium into the acinar cell and enhancing the secretion of digestive enzymes [21]. This appears to be a key event in the development of cigarette smoke-associated acute and chronic pancreatitis since pancreatic acinar cell damage can be observed experimentally following prolonged nicotine treatment [22]. While the mechanism is not well described, the influence of nicotine on calcium signaling also promotes tumor cell viability, even after the development of pancreatic cancer [23].

Apart from calcium signaling, nicotine also exerts its effects through other pathways and cell types. Nicotine activates stellate cells via α7 nAChR-mediated JAK2/STAT3 signaling inducing pancreatic fibrosis and promoting the differentiation of myeloid-derived suppressor cells to tumor-associated macrophages and dendritic cells, thus supporting carcinogenesis [24,25]. Of note, treatment of pancreatic ductal epithelial cells and pancreatic cancer cells with nicotine previously resulted in a dose-dependent secretion of adrenaline and noradrenaline, contributing to cellular proliferation. This nicotine-induced autocrine catecholamine loop was mediated by 3α, 5α, and 7α nAChRs [26].

In addition, pancreatic ductal cells and pancreatic cancers cells secrete the neurotransmitter GABA following combined stimulation with nicotine and catecholamines. GABA can also act as a potent tumor suppressor, mitigating the damaging effects of chronic nicotine exposure in cells coincubated with GABA [27]. Interestingly, nicotine is able to reduce GABA secretion in a time-dependent manner. This is thought to be mediated by downregulation of the GABA-synthesizing enzymes GAD65 and GAD67 in a 4α nAChR-dependent manner, abrogating the GABA-induced growth inhibition [27].

In addition to its effects on cellular proliferation, nicotine also influences the ability of tumor cells to migrate, invade surrounding tissues, and metastasize.

In pancreatic cancer cell lines, cigarette smoke extracts and nicotine induce the expression of MUC4 in a α7 nAChR-dependent manner [28]. MUC4 is a mucin which promotes tumorigenesis and tumor progression. Additionally, MUC4 is aberrantly expressed in pancreatic cancer and its expression is upregulated in progressively worsening pancreatice intraepithelial neoplasia (PanIN) lesions [29].

Nicotine has also been found to stimulate pancreatic cancer growth, invasion, and metastasis by inducing the expression of osteopontin, a secreted molecule expressed in many cancers. Following nicotine-dependent activation of nAChRs, osteopontin confers tumorigenicity to cells, resulting in increased cell survival, cell motility, tumor growth, and metastasis. This effect is mitigated in the presence of nAChR antagonists, preventing nicotine-induced osteopontin expression [30]. Nicotine further has the ability to hypermethylate tumor suppressor genes by 7α nAChR and MAP kinase pathways, inducing epigenetic alterations supporting carcinogesis [31], and can induce epithelial–mesenchymal transition (EMT) in pancreatic cancer cells [32].

These pathways represent only a fraction of the pathways involved in cigarette smoke-associated pancreatic damage. The carcinogenic effects that are conveyed to many different types of cancer are not specific to the pancreas. Therefore, pancreas-specific effects of cigarette smoke must be involved, rendering the pancreas susceptible to damage from cigarette smoke. These effects are also mediated by the activation of nAChRs that regulate the secretory function of the pancreas. This is evident when cholecystokinin (CCK)-stimulated acinar cells are treated with nicotine, resulting in a reduction of CCK-stimulated amylase secretion [33].

Additionally, it has been shown that chronic nicotine treatment not only reduces the secretion of amylase but also increases the intracellular amylase content in pancreatic acinar cells [34]. Somewhat similar observations were made with cigarette smoke inhalation over a period of 12 weeks. Cigarette smoke inhalation induced a dose-dependent increase in trypsinogen expression but did not influence the expression of genes associated with pancreatic ductal cells [35]. These secretory alterations were associated with focal inflammatory lesions detected throughout the pancreas [36]. When nicotine treatment was performed over a prolonged period in mice carrying a constitutively active *k-ras* gene, comparable effects were observed in the pancreas. Nicotine treatment in conjunction with active *k-ras* induced pancreatic acinar cell damage leading to higher grade PanIN lesions and increased acinar-to-ductal metaplasia [37]. This was associated with a loss of GATA6 expression that could be reversed by metformin. After full transition to pancreatic cancer cells, nicotine induced a cancer stem cell phenotype by interacting with α7 nAChR and further induced EMT, promoting cell migration. Similarly, these effects were also reversible with GATA6 overexpression [37]. These pathways appear to be crucial steps in cigarette smoke-induced pancreatic damage. Another mechanism by which nicotine leads to pancreatic cancer progression and metastasis is by inducing MUC4 expression in a dose-dependent manner [28].

Even though pancreatic inflammation and acinar-to-ductal metaplasia are very likely to be associated with pancreatic carcinogenesis, nicotine alone is not the sole factor in tobacco-associated pancreatic carcinogenesis but enhances its occurrence. Acinar cell stimulation plays an important role in these mechanisms since the stimulation of acinar cells by CCK also significantly increased the rate of pancreatic cancer formation, indicating that nicotine may enhance the fatal action of carcinogens by altering the secretory function of acinar cells.

Other carcinogens are also able to induce acinar-to-ductal metaplasia. This has been demonstrated in rodent models of ductal adenocarcinoma in which 7,12-dimethylbenz(a)anthracene (DMBA) crystals are surgically implanted in the pancreatic tissue. In this model, histologic alteration of the exocrine pancreas was observed, described as tubular complexes, representative of acinar-to-ductal metaplasia [38].

In summary, experimental evidence of cigarette smoke-induced pancreatic carcinogenesis can be placed into two categories. The first is that carcinogens can induce genetic or epigenetic changes resulting in DNA damage. Second, carcinogens mediated their pharmacologic effects through nACh receptors. The latter can be further subcategorized. The first subset of nAChR-dependent mechanisms centers on the enhancement of procarcinogenic events mediated by a variety of substances. The second subset of mechanisms involves alterations in acinar cell secretory function, contributing to the development of pancreatic inflammation.

Clinical Data Supporting the Experimental Findings

Clinical data on cigarette smoke-induced pancreatic damage largely consists of epidemiologic correlations between smoking, pancreatic inflammation, and cancer. Some of the key elements, such as carcinogen accumulation and interference with the regulation of pancreatic enzyme secretion, have been confirmed in clinical studies. Prior research has demonstrated that carcinogens do accumulate in pancreatic juice of smokers. In these

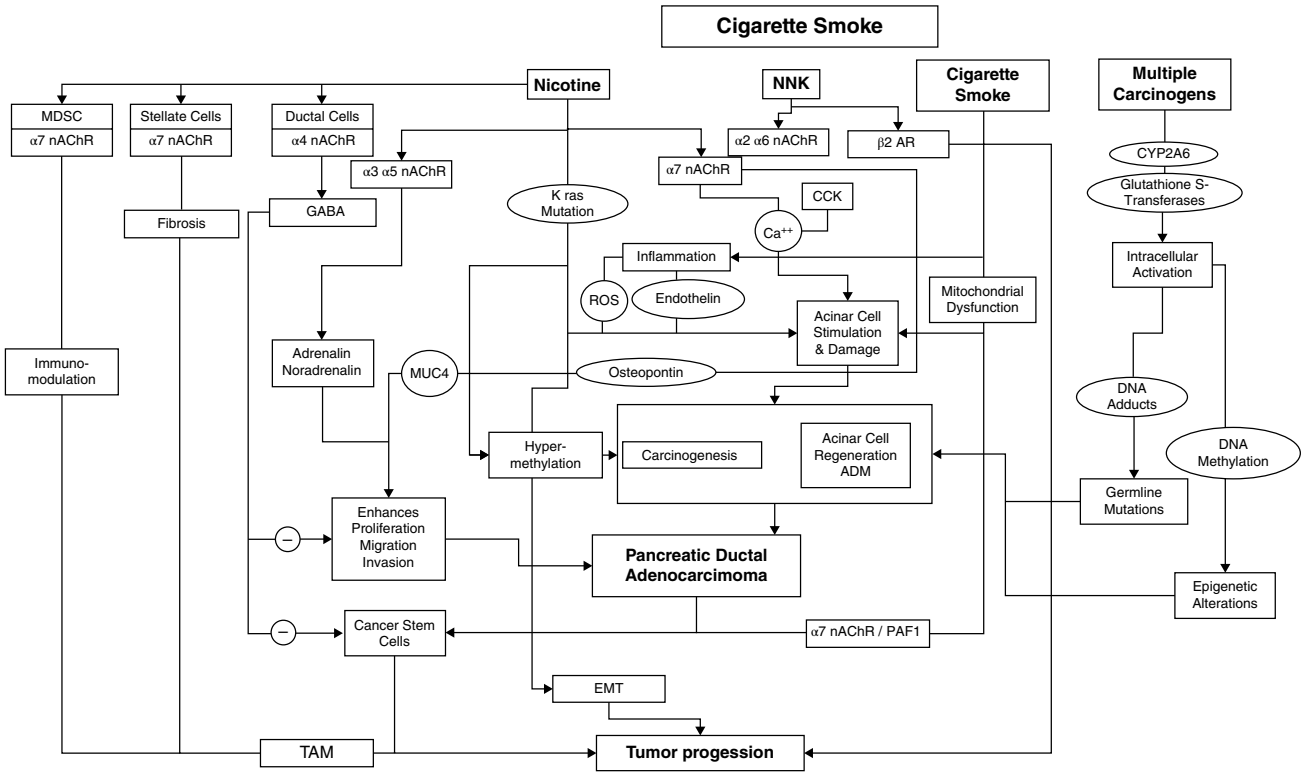

Figure 118.1 Summary of experimental and clinical data on the effects of cigarette smoking on pancreatic carcinogenesis. The pharmacologic activity of cigarette smoke on the pancreas is mediated by nicotinergic acetylcholine receptors (nAChR) and induces pancreatic acinar cell damage and mediates a variety of adverse events. In addition to that, the carcinogenic action is induced after the intracellular activation of carcinogens by cytochrome P450 enzymes. Glutathione transferases seem to be involved in the intracellular detoxification.

studies, NNK was detectable in 83% of smokers [39]. Previous studies have also demonstrated that inhaled carcinogens are delivered to the pancreas and that enzymes metabolize these compounds into active electrophiles, at which point they can exert their genotoxic properties within the pancreas [40]. As an example of their clinical relevance, the phenotypic variation of carcinogen-metabolizing enzymes, such as CYP450 2A6, influenced the pathogenesis of pancreatic cancer. In an adjusted categorical analysis, subjects in the uppermost quartile of CYP2A6 activity carried an 80% greater risk of acquiring pancreatic cancer [41].

Similar observations have been made for glutathione S-transferases (GSTs), a family of phase II isoenzymes believed to protect cells from reactive chemical intermediates [42]. In this study, the adjusted odds ratios of pancreatic cancer for heavy smokers with the GSTT1-null genotype were 5.0 (95% confidence interval [CI] 1.8–14.5) for women and 3.2 (95% CI 1.3–8.1) for men, indicating that the combination of heavy smoking and a deletion polymorphism in GSTT1 is associated with an increased risk of pancreatic cancer.

Tobacco-derived carcinogens are undoubtedly involved in the carcinogenesis of pancreatic cancer. While 32P-postlabeling analysis indicates a specific adduct pattern in smokers, increased adducts in pancreatic DNA were observed in smokers but an association with BMI was also observed [43]. No clear association of DNA adducts in the pancreas with the individual smoking history utilizing chromatography has yet been established. This could be due to the relatively limited amount of DNA adducts present or this quantity being below the limit of detection [39,40]. Independent of detection method, nonsmokers must also be exposed to many environmental carcinogens, inducing the formation of DNA adducts similar to those observed in smokers.

Similar to experimental observations, cigarette smoke exerts widespread pharmacologic effects on the human pancreas which are mediated by nicotine and other tobacco-derived carcinogens displaying pharmacologic activities. In the 1970s, the relationship of cigarette smoking with the pancreatic secretion was discovered [44]. In a clinical experiment, smoking induced immediate and reproducible effects on the pancreatic secretion in volunteers. After smoking cigarettes, the fluid and bicarbonate secretion was immediately altered and returned to normal within 30–60 minutes. This effect directly correlated with the serum nicotine concentration. In accordance with this observation, cotinine, a derivate of nicotine with a longer half-life, was detected in the pancreatic juice of active smokers with an average concentration of 129<ts>ng/mL [39]. The concentration of these compounds has not been measured in pancreatic tissue, but the differential expression of nACh receptors has been demonstrated on human pancreatic acinar and ductal cells [17,26].

The effects of cigarette smoke on pancreatic exocrine function are thought to be responsible for the induction of pancreatic acinar cell damage and have been shown to have a clear association with both acute and chronic pancreatitis [45]. While a small subset of patients experience inflammation of the entire gland, in most patients the cigarette smoke-induced pancreatic damage is only present in small focal areas of the pancreas where remodeling is occurring at the same time as sample acquisition. Similar to experimental data, an increase in small inflammatory foci with ongoing pancreatic regeneration was observed in humans as well. In this context, focal acinar cell dysplasia has been described at the time of autopsy and in surgical specimens. These acinar cell lesions were found to be acquired and correlated to history of smoking. Additionally, they were detectable in 83% of heavy smokers [46]. Acinar cell lesions are also associated with simple and atypical ductal hyperplasia, indicating that either the cigarette smoke-induced damage leads to ductal lesions as well, or it can be speculated that these ductal lesions are the result of acinar-to-ductal metaplasia [47].

Conclusion

Today evidence for cigarette smoke-induced pancreatic disease remains incomplete, but available experimental and clinical data propose potential pathomechanisms of cigarette smoke-induced pancreatic carcinogens that remain to be further investigated in both experimental and clinical studies. The pancreas is susceptible to the effects of carcinogens found in cigarette smoke partly as a result of acetylcholine receptor-mediated events, or by mutations, e.g., of tumor suppressor genes. These contribute to the induction of proliferative signaling pathways and pancreatic inflammation. These events provide a fertile environment for pancreatic ductal adenocarcinoma to develop, at which point the smoking history appears to have no impact on the clinical course [48]. However, patients who continue to smoke following surgical resection of a ductal adenocarcinoma have an increased perioperative risk and decreased survival compared to individuals who refrain from smoking [49]. The fact that the risk sharply decreases after smoking cessation and a risk similar to never smokers is reached after approximately 15 years may encourage smokers to stop smoking [2,50].

Molecular Understanding of the Development of Ductal Pancreatic Cancer

Jae W. Lee, Ralph H. Hruban, and Laura D. Wood

Departments of Pathology and Oncology, The Sol Goldman Pancreatic Cancer Research Center, The Johns Hopkins University School of Medicine, Baltimore, MD, USA

Introduction

Pancreatic cancer is the third leading cause of cancer in the United States and is predicted to be the second leading cause of cancer death by the year 2030 [1,2]. A fundamental understanding of the molecular underpinnings of pancreatic cancer will not only provide insight into the pathophysiology driving this neoplasm, but will also provide new tools that can be used to detect early curable pancreatic neoplasms and to treat advanced cancers.

The groundwork for our understanding of the genetic drivers of ductal adenocarcinoma was laid decades ago, but this knowledge has exploded in recent years. The first gene identified as targeted in ductal adenocarcinoma was the *KRAS* oncogene in the mid-1980s [3–5]. It took almost another decade before the *TP53* tumor suppressor gene was shown to be inactivated in most of these cancers [6,7]. In the 1990s, a team led by Scott Kern extensively characterized the allelic losses in a series of ductal adenocarcinomas and identified a number of recurrent genetic alterations, including homozygous deletions on chromosomes 9p, 13q, and 18q that correspond to three additional tumor suppressor genes [8–10]. The homozygous deletion identified on chromosome 9p proved to target the *p16*/*CDKN2A* tumor suppressor gene, the deletion on 13q led to the discovery of the *BRCA2* gene, and the homozygous deletion on 18q led to the discovery of *SMAD4* [11,12]. Thus, by the mid-1990s the four genes most frequently targeted in ductal adenocarcinomas had been discovered (*KRAS*, *TP53*, *SMAD4*, *p16*/*CDKN2A*), as had one of the major familial pancreatic cancer genes (*BRCA2*). Over the ensuing decade, a number of additional genes were found to be targeted in ductal adenocarcinomas, often using candidate gene approaches [13–15]. Most of these proved to be low-prevalence genes (altered only in a small fractions of the cancers), such as *BRAF* and *FBXW7* [15].

The draft map of the human genome was completed in 2001, providing a foundation for dramatically changing the pace of gene discovery in ductal adenocarcinomas [16]. Jones and colleagues used the draft map to Sanger sequence the complete exomes of a series of 24 well-characterized ductal adenocarcinomas, providing a first complete catalogue of protein-coding mutations in this cancer type [17]. This work had several important results: the oncogene *KRAS* and the tumor suppressor genes *TP53*, *SMAD4*, and *p16*/*CDKN2A* were confirmed to be the most commonly targeted "mountains" in ductal adenocarcinoma (Table 119.1), and a number of "hills" with less prevalent mutations were also identified (Table 119.2). In addition, the Jones study led to the discovery of a familial pancreatic cancer gene (*PALB2*) [18–20]. For the first time, a comprehensive understanding of the genetic drivers of pancreatic tumorigenesis was possible. A number of large-scale studies followed, and in recent years several groups, including the Pan-Cancer Analysis of Whole Genomes (PCAWG), the International Cancer Genome Consortium (ICGC), and the Cancer Genome Atlas (TCGA), have extended Jones' whole-exome sequencing study by sequencing the exomes and even whole genomes of ductal adenocarcinomas [21–25]. The time is now ripe to translate this understanding to patient care.

Table 119.1 "Mountains" of pancreatic tumorigenesis.

Gene	Chromosome	Gene type	Function	Mechanism of alteration
KRAS	12	Oncogene	MAPK signaling	Point mutation (hotspots)
P16/CDKN2A	9	Tumor suppressor	Cell cycle regulation	Point mutation/LOH, homozygous deletion, methylation
TP53	17	Tumor suppressor	DNA damage response	Point mutation/LOH
SMAD4	18	Tumor suppressor	TGF-β signaling	Point mutation/LOH, homozygous deletion

LOH, loss of heterozygosity; MAPK, mitogen activated protein kinase; TGF-β, transforming growth factor β.

Table 119.2 Examples of genetic "hills" of pancreatic tumorigenesis.

Gene	Mechanism of alteration	Prevalence/tumor type
AKT2	Amplification	10–20%
ARID1A	LOH + IM	5–10%
ARID2	LOH + IM	<5%
ATM	Often germline	<5%
AXIN1	LOH + IM	<5%
CTNNB1	LOH + IM	<5%
EP300	LOH + IM	<5%
FBXW7	LOH + IM	<5%
GATA6	Amplification	10%
GNAS	Point mutation	Colloid variants
MAP2K4	LOH + IM	<5%
MLL3	LOH + IM	5–10%
MYB	Amplification	10%
MYC	Amplification	5%
PBRM1	LOH + IM	<5%
ROBO2	A number	5–10%
SMARCA2	LOH + IM	Undifferentiated with rhabdoid
SMARCA4	LOH + IM	Undifferentiated with rhabdoid
TGF βR1	HD	<5%
TGF βR2	HD, LOH + IM	Microsattelite unstable cancers

HD, homozygous deletion; IM, intragenic mutation; LOH, loss of heterozygosity.

Genetic Alterations: The Four Mountains

KRAS

The *KRAS* oncogene is activated in >90% of ductal adenocarcinomas, usually by a point mutation at codon 12, 13 or 61 [26]. *KRAS* gene mutations activate a complex cascade of downstream signaling pathways, including the mitogen activated protein kinase and phosphoinositide 3′-kinase pathways [27–30]. *KRAS* gene mutations also contribute to the "Warburg effect" and increase autophagy in the neoplastic cells [27–29]. The resultant changes caused by *KRAS* gene mutations combine to promote tumorigenesis.

KRAS wild-type ductal adenocarcinomas can have other distinctive genetic alterations [15,31]. Some *KRAS* wild-type tumors harbor *BRAF* mutations, and others, as will be discussed in greater detail below, are microsatellite unstable [15,22,31] or harbor kinase fusion genes [32].

p16/CDKN2A

The *p16/CDKN2A* tumor suppressor gene on chromosome 9p is inactivated in 90% of ductal adenocarcinomas [8,33]. In ~40% of the cancers, the gene is inactivated by an intragenic mutation in one allele coupled with loss of the second allele (loss of heterozygosity, LOH). In another 40%, the *p16/CDKN2A* gene is inactivated by homozygous deletion, and in 10–15% of the cancers it is inactivated by hypermethylation of the *p16/CDKN2A* gene promoter [33,34]. Loss of p16 protein function leads to loss of a major regulator of the cell cycle. The *MTAP* gene on chromosome 9p is often included in the homozygous deletions that target *p16/CDKN2A* [35]. As will be discussed later, the deletion of *MTAP* has potential therapeutic implications.

TP53

The *TP53* tumor suppressor gene on chromosome 17p is inactivated, usually by an intragenic mutation in one allele coupled with LOH in the remaining allele, in ~75% of ductal adenocarcinomas [18,36]. Loss of p53 function disrupts a number of critical tumor suppressive pathways, including response to DNA damage, apoptosis, cell cycle arrest, and senescence [37]. Aberrant protein expression patterns, as seen on immunohistochemical

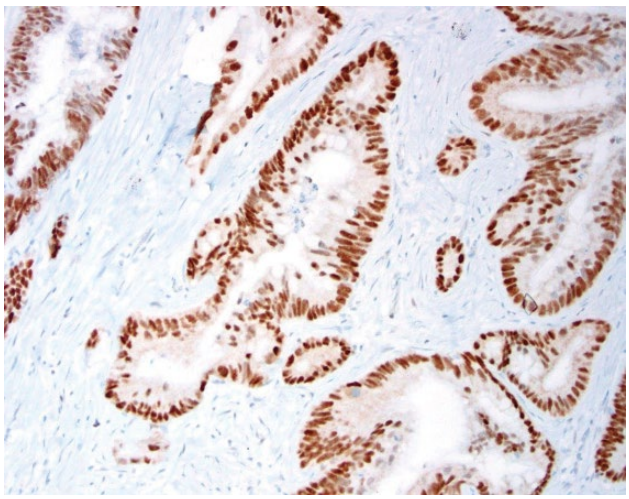

Figure 119.1 Aberrant p53 protein expression in *TP53* mutant ductal adenocarcinoma. Immunohistochemistry for p53 shows strong diffuse nuclear labeling, which is strikingly different from the occasional weak nuclear labeling seen in the nonneoplastic stromal cells.

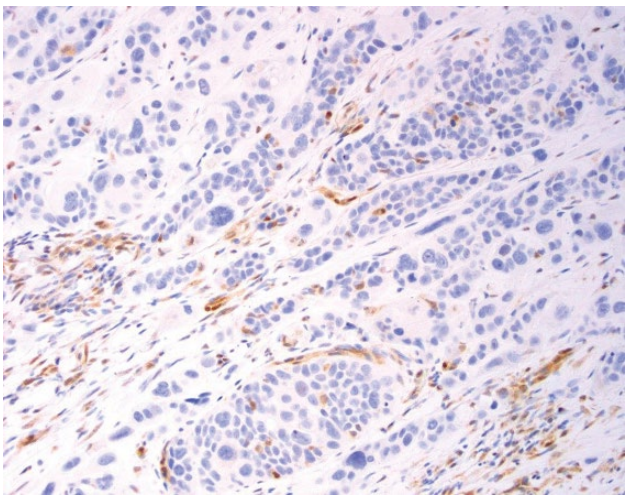

Figure 119.2 Loss of SMAD4 protein expression in *SMAD4* mutant ductal adenocarcinoma. Immunohistochemistry for SMAD4 shows loss of protein expression in malignant cells, while retained expression in nonneoplastic stromal cells serves as an internal control.

assays, are correlated with gene mutation—these include strong diffuse nuclear expression (Fig. 119.1) as well as complete absence of expression.

SMAD4

The *SMAD4* tumor suppressor gene on chromosome 18q is inactivated in ~55% of ductal adenocarcinomas [12]. As noted earlier, *SMAD4* was discovered by Scott Kern and colleagues as a recurrent homozygous deletion identified using a panel of microsatellite markers [12]. Subsequently, *SMAD4* has been shown to encode a protein that functions in the transforming growth factor (TGF)-β pathway. Immunolabeling for the SMAD4 protein is a good surrogate marker for *SMAD4* gene inactivation, as inactivating mutations in *SMAD4* are associated with loss of SMAD4 protein expression (Fig. 119.2) [38].

Genetic Alterations: The Hills

In addition to the four "mountains" (the four genes targeted in >50% of pancreatic cancers), a growing number of genes have been found that are altered in only a small fraction (usually <10%) of ductal adenocarcinomas (see Table 119.2) [18,22–24]. For example, Biankin and colleagues sequenced the exomes of close to 100 ductal adenocarcinomas and reported that genes coding for embryonic regulators of axon guidance, including *ROBO* and *SLIT*, are targeted in a minority of these cancers [23]. Sausen and colleagues reported uncommon mutations in chromatin regulating genes (such as *MLL3* and *ARID1A*) that are associated with improved survival [39]. Others have reported focal gene amplifications in ductal adenocarcinomas, including amplification of *MYC*, *GATA6*, *BRAF*, *CDK6*, and *MET* [24,40-42]. Genetic alterations in *p15/CDKN2B*, *CCNE1*, and *MAP2K4* have also been reported [21].

Chromosome Instability

In addition to the specific genes noted above that are targeted by focal chromosomal alterations, ductal adenocarcinomas of the pancreas are also characterized by larger chromosome abnormalities [24,43,44]. These larger chromosome abnormalities were first noted in karyotyping studies of pancreatic cancer [43]. Subsequently, the exact loci involved were defined better in whole-genome sequencing studies [24]. These latter studies also showed that chromosome instability is associated with the inactivation of DNA maintenance genes (*BRCA1*, *BRCA2* or *PALB2*) and a DNA damage repair deficiency mutational signature [24].

Microsatellite Instability

A small fraction (2–3%) of pancreatic cancers have microsatellite instability, with defective DNA repair pathways leading to a large number of point mutations [31,45,46]. Some pancreatic cancers with microsatellite instability (also known as MSI high cancers) arise

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 119.3 Medullary carcinoma. The characteristic morphology of medullary carcinoma (poor differentiation, syncytial growth, pushing borders) is frequently seen in tumors with microsatellite instability.

in association with intraductal papillary mucinous neoplasms (IPMNs) and others have a characteristic medullary histology that includes poor differentiation, a syncytial growth pattern, and pushing tumor borders (Fig. 119.3) [45]. These carcinomas are important to recognize because, despite their poor differentiation, they are associated with a good prognosis [45,46]. In addition, as will be discussed later, MSI high pancreatic cancers may be particularly sensitive to immunotherapies [47].

Kinase Gene Fusions

KRAS wild-type ductal adenocarcinomas frequently harbor kinase gene fusions. Various gene fusions involving *BRAF*, *FGFR2*, *RAF1*, *ALK*, *RET*, *NTRK1*, *ERBB4*, *FGFR2*, *EGFR*, and *MET* have been identified in 12% of *KRAS* wild-type ductal adenocarcinomas [48]. In many of these gene fusions, a serine/threonine kinase or tyrosine kinase catalytic domain is fused to an oligomerization domain [48]. In addition to gene fusions mentioned above, *NRG1* gene fusions have also been reported in *KRAS* wild-type ductal adenocarcinomas [49–51]. *NRG1* gene fusions promote tumor proliferation and survival by activating pathologic signaling via MAPK, PI3K-AKT, and NF-κB [32]. Though data are still limited, pancreatic cancer patients with cancers that harbor gene fusions may benefit from targeted kinase inhibitors. For example, pancreatic cancer patients with cancers with *NRG1* gene fusions have shown significant response to afatinib [50] and erlotinib/pertuzumab [51], and patients with cancers with *ALK* gene fusions have demonstrated stable disease after treatment with ceritinib [52].

Taken together, these studies highlight the importance of identifying a subset of patients whose pancreatic cancers harbor gene fusions, as they may benefit from specific targeted pharmacologic agents.

Mitochondrial Gene Mutations

Although we tend to focus on the nuclear genome, eukaryotic cells also have a mitochondrial genome. Jones and colleagues sequenced the mitochondrial genome (mtDNA) of a series of pancreatic cancers, and homoplasmic mtDNA somatic mutations were identified in nearly all of the cancers [53]. While it could not be determined if any of these mtDNA mutations were driving the neoplastic process, Jones and colleagues were able to show that mtDNA is greatly (6–8-fold) increased in ductal adenocarcinoma cells relative to normal cells. This finding suggests that mtDNA mutations may be easier to detect than nuclear mutations and that mtDNA mutations may be useful in screening and disease monitoring tests [53,54].

Expression Changes

A number of genes are overexpressed in ductal adenocarcinomas relative to normal nonneoplastic pancreatic ductal cells [55–61]. Many of these overexpressed genes were identified at the mRNA level using techniques such as serial analysis of gene expression (SAGE) and expression microarrays, and protein overexpression has been confirmed using Western blotting or immunohistochemical labeling [55–61]. Other overexpressed proteins were discovered using mass spectrometry and other proteomic approaches [62]. Transcriptomics studies based on gene arrays and RNA sequencing have also demonstrated that pancreatic ductal adenocarcinomas have distinct subtypes, including basal-like and classic subtypes [63]. While basal-like subtype (median survival time of 11 months and one-year survival rate of 44%) is associated with worse outcome compared to classic subtype (median survival time of 19 months and one-year survival rate of 70%), patients with basal-like tumors have shown better response to adjuvant chemotherapy [63]. Additional molecular subtypes have also been described in recent studies based on RNA and DNA sequencing [64].

The list of genes and proteins overexpressed in ductal adenocarcinomas is long and includes mesothelin, claudins, annexins, S-100 related proteins, and others [57,65–70]. Pandey and colleagues have reviewed the literature and established a centralized resource for the collection and sharing of these overexpressed genes [71,72]. More recently, a "proteogenomic" study that integrated

Table 119.3 Precursors to ductal adenocarcinoma.

Precursor	Abbreviation	Location	Size	Key genetic alterations
Pancreatic intraepithelial neoplasia	PanIN	Head = Tail	<0.5 cm	Early: *KRAS*, *CDKN2A* Late: *TP53*, *SMAD4*
Intraductal papillary mucinous neoplasm	IPMN	Head > Tail	≥1 cm	Early: *KRAS*, *GNAS*, *KLF4*, *RNF43*, *CDKN2A* Late: *TP53*, *SMAD4*
Mucinous cystic neoplasm	MCN	Tail > Head	Broad range	Early: *KRAS*, *RNF43*, *CDKN2A* Late: *TP53*, *SMAD4*

proteomic, phosphoproteomic, and glycoproteomic analyses with whole-genome, whole-exome, methylation, and RNA sequencing was completed [73]. This comprehensive study not only provides a number of candidate biomarkers but also sheds light on the impact of genetic alterations on protein expression and posttranslational modifications [73]. As discussed below, differentially expressed genes may be useful targets for developing early detection tests and novel therapies. The technologies to quantitatively distinguish peptides are now so refined that normal proteins can be distinguished from mutant proteins created by some of the DNA mutations discussed above [74].

In addition to overexpressed genes, a number of genes are downregulated in ductal adenocarcinomas. Promoter hypermethylation often accounts for this downregulation [75]. Genome-wide analyses of DNA methylation in ductal adenocarcinomas have identified over 1000 genes that are differentially methylated in pancreatic cancer relative to normal pancreatic ductal cells, and many of these differentially methylated genes are differentially expressed at the protein level [75,76].

MicroRNAs are small noncoding RNAs that have emerged as important regulators of a number of cell functions, and the expression of a number of microRNAs is dysregulated in ductal adenocarcinomas of the pancreas [77]. These microRNAs include miR-21, miR-101, miR-155, miR-192, miR-193, miR-194, miR-196, miR-210, and miR-335 [77,78]. Some of these microRNAs have been proposed as prognostic markers and may also be potential therapeutic targets in ductal adenocarcinomas [79].

Precursor Lesions

Most invasive ductal adenocarcinomas of the pancreas are widely metastatic and incurable at the time of diagnosis [80]. We believe that early detection is one of the best hopes to impact the dismal prognosis associated with these cancers. An understanding of the biology of the precursor lesions that give rise to invasive carcinoma is therefore essential.

Three precursor lesions are currently recognized: pancreatic intraepithelial neoplasia (PanIN), intraductal papillary mucinous neoplasms (IPMNs), and mucinous cystic neoplasms (MCNs) (Table 119.3). A number of studies have examined the genetic alterations and gene expression changes in these precursors, and increasing degrees of dysplasia are associated with the accumulation of genetic alterations and changes in gene expression [78,81–83]. Lesions with high-grade dysplasia have many of the same changes that are found in invasive ductal adenocarcinomas [78,81–83]. For example, most of the microRNAs overexpressed in invasive ductal adenocarcinoma are also overexpressed in precursor lesions with high-grade dysplasia. In addition, studies of IPMNs have shown that when multiple precursor lesions are present, they often arise from independent clones [84], and low- and high-grade lesions have distinct mutations [85]. Specifically, low-grade IPMNs harbor hotspot mutations in *KLF4*, which encodes a member of the Kruppel family of transcription factors [85]. Together, these findings suggest that gene mutations and changes in expression may be useful markers for the early detection of pancreatic neoplasms [78].

Neoplasms with ACINAR DIFFERENTIATION

Although the vast majority of "pancreatic cancers" are ductal adenocarcinomas, malignancies with acinar differentiation do occur, and these cancers are clinically and molecularly unique [86]. Acinar cell carcinomas form solid masses in older adults and have a poor prognosis. Recent whole-exome sequencing studies have revealed

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

that acinar cell carcinomas exhibit striking genomic instability, commonly having either microsatellite instability or chromosomal instability [86]. There is striking heterogeneity in the genes altered among different acinar carcinomas with no single gene mutated in >30% of cancers [86]. Uncommon mutations have been observed in well-characterized drivers of ductal adenocarcinoma (*SMAD4*) and pancreatic cystic neoplasms (*GNAS*), as well as genes commonly altered in other tumor types (*APC*, *BRAF*). Recurrent rearrangements involving *BRAF* and *RAF1* have also been identified in 23% of acinar cell pleuralcarcinomas [87]. Targetable genetic alterations, including *BRCA2*, *PALB2*, *ATM*, and *JAK1*, have also been reported in acinar cell carcinomas [86].

Pancreatoblastoma, the most common pancreatic tumor in childhood, can contain a variety of cell types but at minimum contains an acinar component and squamoid nests. These neoplasms contain far fewer somatic mutations than acinar cell carcinomas, and alterations in the Wnt pathway (*APC*, *CTNNB1*) as well as loss of a highly imprinted region on chromosome 11p are the most common genetic alterations in this tumor type [86,88].

Clinical Applications

These are exciting times. We are on the cusp of translating our growing understanding of the underlying biology of pancreatic cancer to patient care. We anticipate that in the near future, new molecular approaches will be developed to enhance the early detection, diagnosis, treatment, and monitoring of pancreatic cancer. Let us give examples of each of these.

Early detection is one of the most promising areas for the translation of molecular genetics to patient care. For example, mutant *GNAS* shed from noninvasive IPMNs can be detected in secretin-stimulated pancreatic secretions (pancreatic juice) collected at the time of endoscopic ultrasound (EUS) [89]. Similarly, mutant *KRAS* shed from early-stage (operable) ductal adenocarcinomas of the pancreas is detectable in the blood [90]. Panels of new biomarkers, such as tumor-specific genetic mutations, applied to the right biosamples, will provide exciting new opportunities for the early detection of curable pancreatic neoplasms.

Molecular genetics can also be used to supplement tissue diagnoses. For example, in patients with a known pancreatic cancer, it can be difficult to determine if an adenocarcinoma in a distant site, such as the lung, represents a metastasis or a new primary. In these instances, the loss of SMAD4 expression, as determined by immunohistochemical labeling, supports the diagnosis of a metastasis from a pancreatic primary over a second lung primary (see Fig. 119.2) [38].

Remarkable advances have also been made in the application of molecular genetics to personalized therapy of ductal adenocarcinomas. Five examples are listed below.

- Approximately 2–3% of pancreatic cancers are microsatellite unstable (MSI high), and these cancers appear to be remarkably sensitive to immunotherapy, particularly with PD-1 blocking agents [47].
- Most pancreatic cancers overexpress mesothelin, and a number of antimesothelin-specific vaccines [91,92] and chimeric antigen receptor T cells targeting mesothelin [93–95] have been developed.
- Pancreatic cancers with a mutation signature indicative of DNA damage repair deficiency (including those with *BRCA2* mutations) are likely to respond to specific chemotherapeutic regimens, including platinum agents and poly ADP ribose polymerase (PARP) inhibitors [96,97].
- *KRAS* wild-type ductal adenocarcinomas often harbor *BRAF* mutations, and these *BRAF* mutant cancers are highly sensitive to targeted BRAF inhibition [22].
- As mentioned earlier, the *MTAP* gene on chromosome 9p is homozygously deleted with *P16/CDKN2A* in 30–40% of pancreatic cancers. This gene codes for the enzyme methylthioadenosine phosphorylase (MTAP), and MTAP-deficient cells may be differentially sensitive to methylthioadenosine (MTA, the substrate for the MTAP enzyme) and to small molecular inhibition of protein arginine methyltransferase 5 (PRMT5, an enzyme upstream from MTAP) [98,99].

Finally, a molecular genetics approach can be used to monitor patients for response to therapy. Neoplasms release mutant DNA into the circulation (circulating tumor DNA, ctDNA) and this ctDNA can be quantified [39,90]. Velculescu and colleagues have shown that monitoring ctDNA can be used to quantify the response of a neoplasm to therapy [39].

Conclusion

These are the best of times. Hundreds of ductal adenocarcinomas of the pancreas have been sequenced, and the fundamental drivers of tumorigenesis in the pancreas are now defined. These drivers give us new tools for the early detection of pancreatic neoplasms, and it is hoped that these early detection efforts will save lives, especially when applied to high-risk populations, such as individuals with a deleterious germline variant in a familial pancreatic cancer gene. Despite our best efforts at early detection, we recognize that most patients will still be diagnosed with an invasive carcinoma, and new

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. approaches to personalized therapies are needed. These may include immunotherapy for MSI high cancers and poly ADP ribose polymerase inhibitors for *BRCA2* mutant cancers. In the near future, we will also be able to follow the effectiveness of new therapies using novel approaches, such as monitoring circulating tumor DNA (ctDNA). The future is bright!

From Tissue Turnover to the Cell of Origin of Pancreatic Cancer: An Updated View

Bo Kong, Eva Thoma, and Christoph W. Michalski

Department of Surgery, Ulm University Hospital, Ulm University, Ulm, Germany

Introduction

Pancreatic ductal adenocarcinoma (PDAC) is highly aggressive [1]. Despite enormous advances in understanding molecular tumor biology, the overall survival rate of PDAC patients has remained unchanged for the past 20 years. This may be partially attributed to the fact that PDAC is a histopathologically defined tumor entity with extreme heterogeneity on clinical, histologic, transcriptional, and genetic levels. Various molecular subtypes with distinctive tumor biologies exist, but current therapies are applied without taking these putative differences into account [2].

Pancreatic ductal adenocarcinoma originates from the exocrine cells of the pancreas containing mainly acinar and duct cells. The exocrine cells constitute the predominant cell mass of the human pancreas, in which approximately 70% of all pancreatic cells are acinar cells and 18.5% are ductal cells [3]. As described before, acinar cells produce a variety of digestive enzymes (i.e., amylase and lipase) and duct cells generate bicarbonate and transport the digestive enzymes to the duodenum [4]. Thus, dissecting exocrine cells' self-renewal and regenerative capacities is essential to our understanding of pancreatic physiology and carcinogenesis.

Both ductal and acinar cells display considerable heterogeneity in the human and murine pancreas. Based on the subtle difference in transcriptional profiles, acinar and duct cells can be further categorized into subpopulations with different self-renewal and regenerative capacities. Taking advantage of single-cell analysis with advanced bioinformatic tools, we are now beginning to understand the biological significance of such cellular heterogeneity within the same cell type. In addition, several rare stem/progenitor cells with uni- or multipotent differentiation potential, which are usually not abundant enough to be visible in single-cell analysis, were recently identified in both the acinar and duct compartments. They also contribute significantly to physiologic tissue turnover, organ regeneration upon severe tissue damage, and pancreatic carcinogenesis [5,6].

Previously, we hypothesized that a subset of cells that renew the adult organ physiologically or regenerate it after acute pancreatitis would be more susceptible to oncogenic transformation than others [7]. Here, we provide an updated view on this issue, focusing on literature published after 2015. In addition, as the cell of origin is implicated as a significant source of PDAC heterogeneity for the molecular tumor subtypes, we also summarize and discuss the recent literature on this topic.

Molecular and Phenotypic Characterization of Acinar- and Duct-Derived PDAC

Despite its heterogeneity, most human PDACs contain so-called founder/driver mutations, including oncogenic KRAS mutations (e.g., $KRAS^{G12D}$) and mutations in tumor suppressors (e.g., p53 and p16) [8]. These founder mutations can be induced in the adult pancreas in a cell type-specific manner (e.g., acinar and duct cells); they have been widely used to generate acinar- and duct-derived PDAC models.

Apart from founder mutations, recent *in vivo* studies revealed that the general risk factors for PDAC, such as pancreatitis, promote pancreatic carcinogenesis. Mature pancreatic acinar cells are primarily refractory to transformation following activation of oncogenic Kras [9]. It has also been shown that Kras mutations appear in the pancreas of healthy individuals [10]. This supports the notion that oncogenic Kras alone is insufficient for

induction of carcinogenesis, and a transformation-permissive environment needs to be established first. Indeed, in the presence of acute or chronic inflammation (e.g., as induced by caerulein injection), pancreatic acinar cells in the adult pancreas become susceptible to oncogenic Kras-mediated transformation [9].

Here, pancreatic acinar cells undergo a metaplastic process called acinar-to-ductal metaplasia (ADM) induced by oncogenic Kras and an (external) inflammatory stimulus. Under physiologic circumstances, ADM is the default and reversible metaplastic process in which acinar cells transiently adopt a ductal phenotype with the acquisition of progenitor-like features, and they are capable of redifferentiating into acinar cells. However, in response to oncogenic Kras signaling and caerulein-induced pancreatitis, this metaplastic phenotype of acinar cells is irreversible. The ADM lesions progress into pancreatic intraepithelial neoplasia (PanIN) lesions and eventually into PDAC, forming a distinctive acinar–ADM/PanIN–PDAC transformation pathway [11–13].

However, pancreatic duct cells cannot initiate PDAC development in such a model derived by oncogenic Kras and caerulein-induced pancreatitis [14]. Thus, pancreatic duct cells may assume a specific transformation route in the context of inflammation-driven carcinogenesis, and caerulein-induced pancreatitis is not an appropriate stimulus. To test this, we used another widely used model of pancreatitis—ductal obstruction—as it is a common etiology being both cause and consequence of human chronic pancreatitis [15]. Indeed, ductal obstruction-induced pancreatitis promotes the formation of preneoplastic lesions from the pancreatic ductal compartment. These duct-derived preneoplastic lesions show a highly proliferative potential with persistent activation of the intrinsic inflammatory pathway; however, no PanIN lesions were observed in these animals. Instead, these preneoplastic lesions presented in tubular complex structures surrounded by desmoplastic stroma. Likely, pancreatic duct-derived PDAC follows a transformation pathway bypassing the PanIN stage (see below). Later on, these observations were confirmed by another independent study published by Shi and co-authors [16]. Taken together, the type and extent of inflammation determine whether PDAC can be initiated from pancreatic acinar or duct cells.

Having illustrated that pancreatic duct and acinar cells can initiate PDAC in mice, four independent studies have systematically compared acinar- and duct-derived tumors (Table 120.1) [17–20]. In 2016, Bailey and co-workers used the Hnf1b^{CreERT2} (HNF1 homeobox B) and Mist1^{CreERT2} (also known as Bhlha15 [basic helix-loop-helix family, member a15]) Cre line to drive Kras^{G12D} and p53^{R172H} mutations in the adult duct and acinar cells, respectively [17]. All mice were injected at 7–9 weeks of age with 5 mg tamoxifen for three consecutive days to induce Cre-mediated genetic recombination. Here, *Mist1^{CreERT2}; LSL_Kras$^{G12D/+}$; LSL_p53$^{R172H/+}$* mice developed acinar-derived ADMs/PanINs and PDACs as early as two months after tamoxifen treatment; however, no duct-derived tumor was observed in *Hnf1b^{CreERT2}; LSL_Kras$^{G12D/+}$; LSL_p53$^{R172H/+}$* mice after six months follow-up. Further experiments uncovered that the expression of two alleles of mutant p53^{R172H} was required to initiate duct-derived tumors: *Hnf1b^{CreERT2}; LSL_Kras$^{G12D/+}$; LSL_p53$^{R172H/R172H}$* mice succumbed to lethal PDAC within 2–3 months and no PanIN lesions were observed in these animals. Histologic evaluation of the respective tumors revealed that acinar-derived tumors are less proliferative but contain better organized collagen deposition adjacent to tumor cells than duct-derived tumors. Moreover, the acinar-derived tumors follow an acinar–ADM/PanIN–PDAC transformation pathway while the duct-derived tumors bypass the PanIN stage. This notion was further verified in Ferreira's study in which they used the Elastase1^{CreERT2} and Krt19^{CreER} Cre lines to mediate genetic recombination in adult acinar and duct cells, respectively (see Table 120.1). As mentioned above, caerulein-induced pancreatitis was used to accelerate acinar-derived PDAC formation in this study. However, these two studies are complicated by either using different genetic drivers (*p53$^{R172H/R172H}$* vs *p53$^{R172H/+}$*) or additional manipulations (with or without pancreatitis) to drive pancreatic carcinogenesis, making a direct side-by-side phenotypic comparison of acinar- and duct-derived tumors impossible.

Later on, this issue was resolved in two studies by Lee and Flowers [19,20]. At 3–4 weeks of age, the same driver mutations (Kras^{G12D} and loss of p53) were introduced to "juvenile" acinar and duct cells using the Ptf1a^{CreERTM} and Sox9-creER^{T2} Cre line, respectively. No additional intervention was performed and all mice were monitored for PDAC development [19]. Here, duct-derived tumors displayed a more aggressive progression pattern than acinar-derived ones, showing earlier tumor initiation and metastasis. In histology, acinar-derived tumors contained a full spectrum of PanIN lesions (PanIN1–3), while duct-derived tumors had only PanIN3 lesions (carcinoma *in situ*). These data suggest that pancreatic duct cells are primed to form carcinoma *in situ*, bypassing the earlier PanIN stages. Interestingly, this phenotypic difference between acinar- and duct-derived tumors disappeared when the above-mentioned driver mutations were introduced to adult acinar and duct cells at 8–10 weeks of age [20].

Taken together, acinar- and duct-derived PDAC are two different tumor entities with potentially different biological phenotypes and progression patterns. Despite certain

discrepancies among different studies, it is rather conclusive that acinar-derived tumors tend to follow a classic transformation route of acinar–ADM/PanIN–PDAC, while duct-derived tumors assume an oncogenic route of duct–carcinoma *in situ*–PDAC, bypassing the PanIN stage.

Tissue Turnover Dynamics and Carcinogenesis in the Exocrine Pancreas

Although adult acinar and duct cells can give rise to PDAC, the exact identity of such mature cells susceptible to transformation still remains unclear. Hypothetically, a subset of cells that renew the adult organ under physiologic circumstances or regenerate it upon severe tissue damage would be more likely to be the cell of origin for PDAC [7]. The recent discovery of telomerase reverse transcriptase (Tert)- and doublecortin-like kinase-1 (Dclk1) cells provides strong evidence for a potential causal link between tissue turnover dynamics and carcinogenesis in pancreatic acinar cells [5,6]. Using lineage tracing from the Tert locus, a rare subpopulation (1.9%) of acinar cells is marked by Tert expression. Of note, Tert-positive acinar cells are responsible for renewing the pancreas under physiologic conditions and quickly regenerating the acinar compartment after acute pancreatitis. Compellingly, expression of oncogenic Kras in Tert-positive acinar cells causes the ADM/PanIN formation with increased Kras downstream signaling [5]. In contrast, expression of oncogenic Kras in random acinar cells had no such effect. Dclk1-positive acinar cells are also rare, accounting for about 0.08–0.4% of all pancreatic epithelial cells [6]. Using genetic lineage tracing, Dclk1-positive subpopulations are long-lived, quiescent acinar cells that do not contribute to the physiologic acinar cell renewal. However, they can be activated by caerulein-induced pancreatitis and contribute to subsequent acinar cell regeneration. Indeed, Dclk1-positive acinar cells are primarily resistant to oncogenic Kras-mediated transformation, but they become potent cancer-initiating cells after acute pancreatitis.

These data collectively demonstrate that the physiologic maintenance of the acinar cell pool is mainly carried out by the Tert-positive subpopulation, and regeneration of the acinar cell compartment upon severe tissue damage requires both Tert- and Dclk1-positive acinar cells. Although both acinar cell subpopulations are rare, they are readily transformable by oncogenic Kras in the context of tissue turnover.

As for the duct compartment, the exact identity of a ductal subpopulation mediating the tissue turnover and contributing to duct-derived tumors remains largely unexplored. Recently, single-cell analysis of human major pancreatic duct uncovered a subpopulation of ductal cells labeled by activin-like kinase3 (ALK3), but not carbonic anhydrase II (CAII) [21]. These human ALK3-positive duct cells can differentiate into all pancreatic lineages upon transplantation into immunodeficient mice. However, further studies are required to elucidate their functions *in vivo*. Notably, Martens and co-authors recently reported a rare and atypical duct cell that expresses the basal cell transcription factor ΔNp63, an isoform of tumor protein P63 (TP63), in the human pancreas [22]. ΔNp63-positive duct cells account for 0.006% of all pancreatic cells, corresponding to 1.6% of duct cells. Given the fact that the basal-like molecular subtype of PDAC also is enriched for ΔNp63 expression and resembles duct-derived tumors at multiple levels (see below), it is likely that the rare ΔNp63-positive duct cells serve as the cells of origin for duct-derived tumors.

Molecular Subtypes of Human PDAC

Three major molecular subtypes consisting of classic, quasi-mesenchymal (QM-PDA), and exocrine-like pancreatic cancers have been initially identified using transcriptional profiles from physically microdissected tumor epithelium (Table 120.2) [23]. The classic subtype shows a high expression of epithelium-associated genes, whereas the quasi-mesenchymal subtype presents a high expression of mesenchyme-associated genes. The exocrine-like subtype expresses relatively high levels of digestive enzymes. Importantly, these three molecular subtypes of PDAC produce different clinical outcomes and therapeutic responses. Patients with the classic subtype tend to have a better prognosis and are more likely to benefit from targeted therapy (e.g., erlotinib), whereas patients with the QM-PDA subtype have a worse prognosis but are likely to respond to conventional chemotherapy (e.g., gemcitabine). Using patient-derived xenograft (PDX) models, HNF1A (HNF1 homeobox A) and KRT81 (cytokeratin 81) were identified as surrogate subtyping markers for exocrine-like and QM-PDA, respectively [24]. Notably, the exocrine-like subtype was largely resistant to tyrosine kinase inhibitors and paclitaxel due to the high expression of CYP3A5 (cytochrome P450 3A5), which is responsible for metabolizing these compounds.

Recently, this transcriptomic classification system has been further developed using a large RNA-sequencing dataset [24]. The original QM-PDA has been reclassified as a squamous subtype as it is associated with adenosquamous carcinomas (only in a small subset of PDACs) on histology. The squamous subtype continues to be a poor prognostic factor, with a median survival of 13.3 months. The exocrine-like subtype is categorized as an aberrantly differentiated endocrine exocrine subtype (ADEX) because

Table 120.2 Summary of molecular subtypes in human PDAC.

Molecular subtype	Applied classifier	Therapeutic hints	Overlap with other defined subtypes
Classic QM-PDA exocrine-like	Transcriptome Physically micro-dissected tumor epithelium	Classic: Erlotinib QM-PDA: Gemcitabine Exocrine-like: resistant to tyrosine kinase inhibitors and paclitaxel	
Squamous pancreatic progenitor Immunogenic ADEX	Transcriptome RNA-sequencing data using bulk tissues	Immunogenic: immune modulators	Squamous = QM-PDA ADEX = exocrine-like Pancreatic progenitor = classic
Basal-like vs classic	Transcriptome Virtually micro-dissected tumor epithelium	None	50% overlap with QM-PDA (squamous)

the transcriptional networks responsible for both exocrine and endocrine lineages at a later stage are enriched in this subtype. Importantly, the classic subtype was defined as a pancreatic progenitor characterized by preferential gene expression in early pancreatic development. Characterized by enriched immune networks related to an acquired immune suppression, a novel immunogenic subtype has been identified. It may potentially be therapeutically accessible to novel immune modulators.

One hallmark of PDAC is the extensive stromal reaction. A recent study performed nonnegative matrix factorization (NMF) analysis to digitally separate gene expression for tumor, stroma, and normal components in PDAC samples [25]. This virtual microdissection identified two molecular subtypes: the classic and basal-like subtypes. The basal-like subtype expresses high levels of basal-like genes (e.g., specific laminins and keratins) similar to basal subtypes in breast cancers [26]. The basal-like subtype labels a PDAC cohort with a median survival of 11 months that most likely benefits from adjuvant chemotherapy (hazard ratio [HR] 0.38; 95% confidence interval [CI] 0.14–1.09). Interestingly, approximately 50% of previously described QM-PDA (squamous) subtypes were basal-like subtypes.

In summary, the basal-like/squamous/QM-PDA molecular subtype labels a cohort of PDAC patients with aggressive tumor biology and poor prognosis; the classic/progenitor molecular subtype shows favorable survival.

Cell of Origin Constitutes a Significant Source of Heterogeneity for Molecular Subtype

Although these studies have consistently proven the existence of molecular subtypes of PDAC, the underlying source of such molecular heterogeneity remains unclear. So far, three major sources have been described: (i) allelic imbalance of KRAS; (ii) differential activation of AP-1 (activator protein-1)-dependent enhancer network; (iii) cell of origin (acinar- vs duct-derived tumors). Initially, an increased dosage of mutant KRAS was reported to be associated with aggressive undifferentiated phenotypes of PDAC [27]. Later on, the integrated whole-genome analysis found that the basal-like/squamous subtype is enriched for KRAS allelic imbalance favoring the mutant allele [28]. Recently, this observation was confirmed in xenograft PDACs generated by intraductal transplantation of human PDAC organoids [29]. Here, human PDAC organoids belonging to the basal/squamous subtype are more likely to contain KRAS imbalance. Secondly, a landmark study by Cobo et al. identified a subclinical inflammatory state of acinar cells, mediated by AP-1 activity and responsible for triggering PDAC initiation [30]. As for the molecular subtype, Tu and co-authors demonstrated that cJUN/AP1 activation and its associated enhancer network were related to basal-like/squamous subtype specification; the JUNB/AP1-dependent enhancer network is enriched in the classic subtype [31].

Importantly, it has recently been demonstrated that different cell origin contributes to the phenotypic and molecular specification of PDAC [19,20,32]. As earlier illustrated, duct-derived PDAC had shorter latency in cancer development, and was associated with a dedifferentiated phenotype, whereas acinar-derived PDAC tended to have a "mild" progression [19]. Furthermore, acinar-derived tumors are positive for KRT20 (keratin 20), which is a putative marker for the classic molecular subtype. This was the first evidence that acinar-derived tumors in mice might be comparable to the classic molecular subtype in humans. Later on, transcriptional analysis revealed that the signatures of duct- and acinar-derived murine PDAC were enriched in the basal-like/squamous and classic molecular

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 120.1 Different transformation routes of acinar- and duct-derived tumors and their counterpart molecular subtypes in humans.

subtype, respectively [20]. A recent study demonstrates that the basal-like/squamous and classic subtypes have distinctive DNA methylation patterns and preserve the remnant footprints of normal ductal or acinar cells [32].

Thus, acinar- and duct-derived tumors are similar to classic and basal-like/squamous molecular subtypes at transcriptional and epigenetic levels. This descriptive evidence points to two different origins, etiologies, and evolutional trajectories of classic and basal-like/squamous molecular subtypes.

Taken together, KRAS allelic imbalance, AP-1-dependent enhancer network, and different cell origins are three major contributors that collectively determine the molecular subtype of human PDAC. Thus, disentangling complex interactions among them is crucial to developing molecular subtype-specific therapies.

Conclusion

As described, acinar- and duct-derived PDAC are likely two different tumor entities with different etiologies and transformational trajectories corresponding to classic and basal-like molecular subtypes in humans. Acinar-derived tumors follow a classic oncogenic route of acinar–ADM/PanIN–PDAC, whereas duct-derived tumors assume a route of duct–carcinoma *in situ*–PDAC, bypassing the PanIN stage (Fig. 120.1). The pancreatic acinar cell compartment is a suitable "sub-organ" system for studying tissue turnover dynamics and carcinogenesis; rare subpopulations (e.g., Tert- and Dclk1-positive) of acinar cells involved in organ renewal/regeneration are readily transformable by oncogenic Kras in the context of tissue turnover. In this respect, more studies on the pancreatic duct compartment are still required.

Microbiome of Pancreatic Cancer: Involvement in Cancer Development and Chemo-/Immunotherapy

Xianjun Yu

Fudan University Shanghai Cancer Center, Shanghai Pancreatic Cancer Institute, Pancreatic Cancer Institute, Fudan University, Shanghai, China

Introduction

The human microbiome drives the tolerogenic innate and adaptive immunity, and resistance to many diseases like diabetes, hypertension, and autoimmune diseases because of its function in maintaining the fine balance in key cellular processes such as inflammation, detoxification, hormones, nutrition, metabolism, and immune. Over the past century, with the revolutionary development of reliable murine models and advanced sequencing technologies, our understanding of the microbiome and its role in cancer initiation and progression has evolved significantly.
